WITHDRAWN

An Address
ON
GUNSHOT WOUNDS AND INJURIES OF THE SPINAL CORD.

Delivered before the Medical Society of London on March 20th, 1916,

BY JAMES COLLIER, M.D. LOND., F.R.C.P. LOND.,

CAPTAIN, R.A.M.C.(T.); PHYSICIAN AND LECTURER IN MEDICINE, ST. GEORGE'S HOSPITAL, ETC.

MR. PRESIDENT AND GENTLEMEN,—I must express my best thanks to you, sir, and to the secretaries of the Medical Society of London for inviting me to open this discussion upon gunshot wounds and other injuries of the spinal cord. The very large number of such cases under our observation during the past 18 months have given us a hitherto unparalleled opportunity to investigate the physiology and pathology of the human spinal cord and the symptoms resulting from its injury. Many new facts have been brought to light and much of our former knowledge thrown into a fresh perspective, and these when time has allowed of their proper working out cannot but cause a valuable advance of our understanding of the spinal cord in conditions of devolution. Necessarily in this country our observations have been made upon cases some time after receipt of the injury, but if we have been denied a scrutiny of the early symptoms we have the advantage of the excellent account of the early conditions given by Colonel Gordon Holmes in the Goulstonian lectures before the Royal College of Physicians. The subject is so large a one that it is impossible that we can in this discussion cover more than a tithe of the points which are of great interest, and therefore I shall make no attempt to deal systematically with the subject, but I shall put before you such items of my individual experience as I hope will excite interest and stimulate discussion. I think it is important in this discussion that any case of injury to the spinal cord which has an important bearing upon the subject should be brought in, whatever may have been the cause of the injury. I am going to introduce one such case myself, and I hope that those who follow me will do so if they wish.

The subjects to which I wish especially to draw attention and to ask for remarks upon are these: (1) The nature and mechanism of production of the lesions; (2) the state of the reflexes and of muscle tone in the affected region; (3) the distinction between root lesions and central lesions of the cord; (4) disturbances of sensibility; (5) prognostic indications; (6) the occurrence of rare and unusual phenomena.

THE NATURE OF THE LESIONS.

The lesions that I have met with have been caused by high-velocity bullets, shrapnel, fragments of shell casing, and by the concussion of high explosives without any external wound. A classification of the lesions, though arbitrary, is, I think, useful in considering the mode in which they are produced. Often more than one kind of lesion is present. The following is a rough classification. 1. Direct lesions. I would define as a direct lesion any lesion resulting from the passage of a missile across the spinal canal whether it touch the spinal cord or not. 2. Indirect lesions: (*a*) Those due to the in-driving of bone, &c., into the spinal canal. (*b*) Impact lesions where the missile strikes against the bony wall of the spinal canal. (*c*) Concussion lesions from the shock of high explosions. 3. Secondary lesions: perithecal and intrathecal hæmorrhage, medullary hæmorrhage and thrombosis, meningitis, œdema. These lesions are important as the cause of the deepening of symptoms often at a considerable time after the injury. 4. Remote lesions which may be found anywhere in the spinal cord and chiefly near the surface: spots of necrosis, sieve-like rarefaction, punctiform hæmorrhages, œdema, swelling of axons. These lesions are produced by the sudden raising of the intraspinal pressure caused by the passage of the missiles through the intraspinal space or by a general concussion effect. They are well marked in cases of concussion without external wound.

The mode of production of the *direct injury* is clear. The passage of a fast-moving projectile through a tissue causes not only a heat effect generated by the friction but an intense raising of the pressure in the tissues for some distance round the track, and if the bullet cross the spinal canal, which contains a fluid pressure, this momentary and severe pressure effect is transmitted to the whole of the nervous system confined within the cerebro-spinal space. The cerebro-spinal space being an elastic cavity the increase of pressure caused by the passage of the bullet will be greatest at the site of the track and will decrease in proportion to the distance from the track, but will be greater below the site of passage than above it, because the lower portion of the spinal canal is more closed and therefore less elastic. The damage to the spinal cord even when the bullet does not touch the cord nor lacerate the membranes is therefore greatest where the bullet has crossed, but it extends for a considerable distance above and below this. Lesions of the cord in places remote from the chief seat of injury are not infrequently found which are attributable to this increase of pressure, and these are always more marked in the distal part of the spinal cord. The intracranial effect of this increase of pressure is the immediate loss of consciousness which is sometimes met with, and more often in cervical injuries than in those lower down. Possibly the initial loss of consciousness may be an index that the bullet traversed the spinal canal. I think that this certainly holds good for the cervical region, for in three of my cases of cervical injury where consciousness was not lost, although the initial symptoms were severe, complete recovery occurred. It seems to me impossible that a bullet can cross the spinal canal without causing the most severe and irreparable of transverse lesions, and I argue that in all the cases where relative or complete recovery occurs the lesion has been an indirect one: either an impact lesion or due to the in-driving of bone. It is likely that a bullet does not so often cross the spinal canal, but is more often deflected by the bony wall.

Mode of production of impact lesion.—The passage of a high velocity bullet in the immediate vicinity of the spinal canal or the impact of a projectile upon the bones forming the spinal canal may cause lesions of the spinal cord sometimes very severe notwithstanding that the walls of this canal remain intact. How are these local concussion lesions produced? The anatomical relations of the spinal cord practically forbid any such displacement of the cord within the canal as could bring it

in contact with the bony wall and so bruise either directly or by contrecoup. Colonel Gordon Holmes has shown that these impact lesions show their greatest intensity immediately under the point of impact and closest to the bullet track as the case may be. I submit the following explanation of the way in which these indirect local lesions of the cord are produced. The contents of the spinal canal which intervene between its parietes and the spinal cord, and made up of the perithecal fat and vessels, the theca and the cerebro-spinal fluid, may be regarded as fluid, and the pressure within the spinal canal as a fluid pressure, contained in a vessel which has one rigid wall, the spinal canal, and one elastic wall, the compressible vessels of the cord, &c. Any lines of force either from excessive vibration, from impact, or from compression transmitted from one spot in the rigid wall will have their most intense effect upon the nearest point of the elastic wall—i.e., the nearest spot in the spinal cord and little elsewhere, the force becoming rapidly spent upon the elastic wall as it radiates. The damage to the spinal cord produced in this way by indirect injury may be from the most severe with symptoms of a total transverse lesion with no recovery, to the slightest with complete recovery. The two following cases are examples of the latter:—

CASE 1.—Patient was hit in left posterior triangle of neck with a rifle bullet. He at once fell paralysed in left arm and leg, but was never unconscious. He came under my care a fortnight after the injury. The skiagram showed the rifle bullet apparently lodged vertically in the odontoid process of the axis. Movements of head and neck were perfectly free and there was no pain. The physical signs were those of strictly unilateral lesion of the left side of the cord at the level of the fifth cervical segment together with a lesion of left fifth and sixth cervical roots. The left arm and leg were spastic, the muscles supplied by the fifth and sixth cervical roots excepted. The left abdominal reflex was absent and the left plantar reflex extensor. The sensory loss was of the usual Brown-Séquard type. It was obvious from his story that he was recovering rapidly when he came under observation both as regards the root lesion and as regards the spinal cord lesion. He made an uninterrupted recovery in the course of two months. In this case the root lesion was probably caused by bruising of the cord formed by the fifth and sixth cervical roots in the posterior triangle and the spinal lesion by the impact of the bullet against the left side of the fourth cervical arch which received a serious jar in that it deflected the bullet from a horizontal to a vertical course. This case shows that the injury to the cord from impact against the bone is directly contiguous to the site of impact.

CASE 2.—Patient was shot by a rifle bullet which traversed the spinal column transversely at the level of the eighth dorsal segment. He was immediately paralysed and completely anæsthetic below the umbilicus. Within 24 hours he began to pass urine naturally, and when he came under my care a week later he had no sphincter trouble, the sensory loss was relative only, and there was some feeble volitional movement of all the muscles of both legs. He has made good progress, and now at the end of three months he can walk well and can run, but somewhat stiffly. The extensor plantar reflexes are still present. It seems to me impossible that the bullet in this case can have entered the spinal canal on account of the small damage to the spinal cord and the completeness of recovery, and I consider that this case was one of an impact lesion from the passage of a high-velocity bullet in the immediate vicinity of the spinal canal.

Concussion lesions.—Severe indirect injuries of the spinal cord may occur from the bursting of high-explosive shells when the back is turned towards the force of explosion without any external wound occurring, without any detectable lesion of the bones, and even without bruising of the soft tissues. I have seen three such cases, of which the following are examples:—

CASE 3.—Patient, crawling forward to the attack on his hands and knees, was for the moment resting prone, with his body stretched upon the ground, when a high-explosive shell burst over him. His consciousness was not affected, and he was able to give me exact details of what happened. At the moment of the bursting of the shell he experienced a sharp tingling sensation in the legs and immediately lost all knowledge of the lower part of his body and legs. He felt no blow upon the back and no pain. He was quite sure that the force of the explosion did not shift his trunk. He told me that the absence of any bruising upon his back was remarked upon by the doctors who examined him in the first place and for the two weeks following his injury. His initial condition was one of total transverse lesion of the cord at the level of the ninth dorsal segment. When I saw him some three months later there had been practically no improvement in his condition. The skiagram showed no abnormality in the bones.

CASE 4.—The history was identical with that of the foregoing case. The patient was, however, rendered unconscious and there was very marked bruising of the back, but the skiagram showed no signs of injury to the spinal column. The clinical picture was that of total transverse lesion of the spinal cord, and there was practically no recovery.

I was not able to follow any of these cases to their termination. In such cases as these, where severe spinal lesions have been produced by the force of high explosion at a distance without any external wound, it is possible to conceive that there has been such distortion of the spinal column as might produce a subluxation of the vertebræ which became immediately reduced, and that during this subluxation the bony rings which make up the spinal canal crossed to such an extent as to produce a severe local transverse lesion of the cord. That such a subluxation is possible has been proved experimentally upon the cadaver, and that it can severely pinch the spinal cord has also been proved, and there is much evidence in the records that such a subluxation, immediately reduced, is one of the lesions that may occur in cases of broken back. I have examined one such case in which a total transverse lesion resulted from a fall from a haystack. The spinal cord was almost severed within the membranes, and although I macerated the bones I could find no sign of fracture. I do not, however, see that there is any evidence in favour of the occurrence of such a subluxation in the cases under consideration, and the histories of the above cases and of several others that I have been told of are against it. We must therefore regard these lesions as impact lesions. It seems remarkable that the impact of the force of the explosion upon the dorsal surface of the body could be sufficient to produce local spinal concussion and a sharply local lesion of the cord without any evidence of severe bruising of the skin and soft tissues. In my three cases and in several others that I have heard of the lesion was in the lower dorsal region. It is a point of great interest as to whether such severe local lesions from explosion occur in other regions, and I should like to ask those present, and especially Dr. Wilson, who is going to tell us about a case that recovered, and Major Mott, who is going to show us the lesions actually produced by this form of injury, in what region of the spinal cord the chief lesion has been found in their cases.

Root lesions.—Sometimes the lesions produced by projectiles affect the spinal roots after they have left the thecal space to a much greater extent than they affect the spinal cord and thecal contents. This seems to me to be the case when there has been much fracture and crushing of the bone, and especially in the region of the transverse processes. There is usually much swelling and œdema in the injured region of the spine. Such root lesions are not entirely due to direct injury, for they may be widely spread when the injury is comparatively local. They may result from subperiosteal hæmorrhages and periosteal swelling, which strangle the roots in the intervertebral foramina, or from pachymeningeal hæmorrhage. Of this last condition—pachymeningeal hæmorrhage—I have had an interesting example.

CASE 5.—Patient was hit by a piece of shrapnel in right lumbar region. The projectile crossed the lumbar spines and came to rest at the left side of the third lumbar vertebral body. There was immediate paralysis of the legs and sphincters with total sensory loss. He came under my care 14 days after the injury. There was total flaccid palsy in both legs in the sciatic supply, with much wasting and loss of faradic excitability. There was feeble power in the quadriceps and adductor groups on both sides. The knee-jerks were absent. There was complete sensory loss over L. 4, 5, S. 1, 2, 3, 4, 5 on both sides. There was complete loss of sphincter control with severe cystitis. There was considerable swelling in the central region of the lower back, and the spines of the third and fourth lumbar vertebræ could be felt to be loose. A laminectomy was performed but was not followed by any marked improvement, though some sensibility was gained in the fourth lumbar areas of both sides and in the fifth on the right side, and after some months the patient succumbed to renal infection.

My diagnosis in this case was that of a lesion of the cauda equina. The necropsy showed that the cauda equina within the theca had not been injured. The anterior roots of the cauda were normal from their points of origin from the cord to their exits from the theca, while the posterior roots from the fourth lumbar downwards were extremely atrophied and grey. The lateral walls of the theca were much thickened, and along the line of the root exits were as much as one quarter of an inch thick. This thickened thecal wall presented in section a sandwich-like appearance, a white tough outer and inner layer enclosing a reddish-yellow softer layer. This condition appeared to have strangled all the sacral and lower lumbar roots, but it did not cease there. It extended along the line of the roots on both sides as high as the upper dorsal region, gradually lessening in intensity, and towards its upper limits the inner surface of the theca was definitely hæmatoidin-stained. The anterior and posterior walls of the theca were only involved in the region of the lumbar enlargement and the cauda equina, and then to a much slighter extent than were the lateral walls along the line of the root exits. It seems to me likely that this condition of pachymeningitis arose from hæmorrhage into the extrathecal roots where these are enclosed in the tube-like prolongations of the theca, and that this hæmorrhage had spread like a dissecting aneurysm between the layers of the spinal theca and had strangled the roots.

Intrathecal hæmorrhage.—Among the many lesions of the spinal cord met with resulting from bullet wounds there are two upon which I should especially like to comment. The first of these lesions is intrathecal hæmorrhage. Blood effused into a free thecal space finds its way with the stream of cerebro-spinal fluid into the lower part of the thecal space around the cauda equina and lumbo-sacral enlargement, and if massive in quantity may distend that space, causing pressure upon the roots and epiconus, and clotting there may cause such matting and cicatrisation as may completely destroy by pressure and evascularisation the cauda equina, and if it extend high enough the lumbar enlargement as well. Smaller effusions by clotting and the formation of condensing adhesions may cause local signs of nerve-root involvement. In a severe condition of this kind where there has been extensive intrathecal hæmorrhage—due, let us say, to a lesion of the mid-dorsal region—the physical signs in the lower extremities may resemble exactly those due to a complete lesion of the cauda equina or of the lumbo-sacral enlargement. In the less severe condition the local deposit and subsequent cicatrisation of blood-clot round individual roots of the cauda may cause physical signs difficult of explanation unless the possibility of the occurrence of intrathecal hæmorrhage and its results are kept in mind. The following is a case in point:—

CASE 6.—Patient was wounded by a bullet traversing spinal canal at level of sixth dorsal segment. Seen two months after the injury, he presented total paralysis with complete sensory loss below the sixth dorsal area, with complete absence of all reflex action and severe wasting of the muscles, none of which responded to faradism. The necropsy showed the caudal part of the theca filled by a mass almost as hard as cartilage and somewhat like cartilage in appearance. It presented no appearance of hæmatoidin staining. Microscopic examination showed it to be an organising coagulum in which the remains of the degenerate nerve roots could be seen embedded. The lumbo-sacral enlargement itself was not embedded in this hard substance, but it showed severe degeneration throughout, evidently from the strangling of the root vessels. Higher up and extending to the sixth dorsal segment the cord was surrounded by a ring of old blood-clot still coloured and firmly adherent both to theca and to cord. The lesion of the cord at the sixth dorsal level was by no means a complete transverse lesion.

It is easy to conceive of cases of thecal hæmorrhage where the matting round the cauda equina is less severe and gives rise to partial lesions of the cauda only, and therefore in cases where the bullet lesion of the spinal cord is above the lumbar enlargement and unusual conditions of reflexes, spasm and contracture are present in the legs it is well to consider whether a condition of thecal hæmorrhage and matting of the cauda equina may not exist. Local wasting of muscles and local loss of faradic excitability may be indications that such a condition exists. The early diagnosis of this condition in such a stage as to allow of the removal of the blood by lumbar puncture and washing out with citrate solution is apparently impossible, for the initial aspect of nearly all the spinal lesions resulting from bullets is that of total transverse lesion, and therefore the development and deepening of the signs of involvement of the cauda equina cannot be detected. In one civilian case, however, I was able to observe the development of such symptoms:—

CASE 7.—Patient had a fracture-dislocation of seventh dorsal vertebra resulting from a fall. He was received into hospital within ten minutes of the accident and was found to have complete paralysis of both legs. Sensation was not deeply affected. The knee-jerks were present and there was an extensor plantar on both sides. Two hours later, when again examined, there was complete flaccid palsy with complete loss of all reflexes and complete loss of sensibility. Unfortunately this was before the days of lumbar puncture. Immediate operation was advised, but the surgeon in whose charge the patient was preferred to wait until the shock had passed off, and when he operated many days later found the theca and cauda equina densely filled with adherent and irremovable clot.

The second remarkable condition that I wish especially to refer to is a condition of *total necrosis of the distal segment* of the spinal cord which was found in one of my patients.

CASE 8.—The lesion was a total transverse lesion at the level of the third dorsal segment. There was total paralysis, total sensory loss and total reflex loss below the lesion, and all faradic excitability was lost. This patient survived for three months. The whole of the distal segment of the cord was completely necrotic and much shrunken, and resembled a strip of greenish yellow wet wash-leather. There was no sign of hæmorrhage, extrathecal or intrathecal, and no sign of any septic process.

I have seen one civilian case in which a condition exactly comparable to the above occurred from fracture-dislocation at the level of the sixth cervical segment in a child. The injury occurred from traction upon the neck during delivery, and the patient survived ten weeks. This case was recorded by the late Dr. Charles Beevor, the pathological report being by Dr. F. E. Batten. Such lesions are very difficult to explain, but the most plausible theory that I can put forward is that a spreading thrombosis throughout the blood-vessels of the distal segment occurs. When one considers that both the anterior and posterior spinal arteries were severed at the site of the injury, and that the injury in both these cases was high in the cord cutting off most of the splanchnic supply and therefore entailing a low blood pressure, and that the tearing of the theca must have deranged the relations of the cerebro-spinal fluid, the possibility of the occurrence of such a spreading thrombosis is conceivable.

REFLEX ACTION.

Time does not permit me to make more than the briefest reference to the condition of the reflexes and of the muscle tone, to contractures and positions of the limbs and to the electrical excitability of the muscles which obtain in the cases under consideration, though the study of these phenomena is one of the most important. It is usually held that the initial condition of reflex action after the occurrence of severe lesion of the spinal cord is that there is complete loss of both jerks and superficial reflexes, or that if the loss is not complete the only sign of reflex action left is a feeble flexor response occurring in the toes, only obtainable from plantar stimulation, and that the early presence of the extensor response or its early return is indicative that the lesion is not complete and is of good prognostic import. I have seen one case which negatives this view. The patient fell from a considerable height, striking his back against the corner of a wall, crushing in four pairs of the upper dorsal laminæ. An operation was immediately performed and showed that some three segments of the spinal cord had been utterly destroyed, the upper and lower ends being found separated by some inches. I examined the patient within a few hours of the injury and repeatedly until his death on the fourth day after the accident, and during this time an extensor response was always present. Colonel Gordon Holmes has laid it down very clearly that the condition of the plantar reflexes in all the cases which he has examined shortly after the injury has been either that they are completely absent or that there is a reduced flexion response, but he is careful to add that his examinations have taken place not earlier than the second day after the injury.

I submit that there may be four consecutive stages in the condition of the plantar reflexes following a transverse lesion of the cord: 1. An initial extensor response. 2. Either a complete absence of any reflex, which may be the result of shock or of isolation alteration, or a reduced flexion reflex which is the result of isolation alteration which may come on rapidly. 3. The extensor response which when persistent is indicative of a less severe lesion or alternatively of more recovery than the reduced flexion reflex. 4. The normal flexion reflex which returns when recovery is complete. I have repeatedly observed the successive changes from no reflex to the reduced flexion response, and from this to the extensor response in cases where some improvement is occurring; and conversely I have seen the extensor response change to the reduced flexion response and the subsequent loss of all reflex action in severe cases which were not improving, and where the only attributable cause for such a change seemed to be the long-standing isolation of the distal segment of the cord. The condition of the plantar reflex is therefore an index of the severity of the damage to the spinal cord and an important early indication as to whether recovery is occurring or not.

Colonel Gordon Holmes has made the very interesting suggestion that the simple flexion of the toes which can be obtained only by stimulating the sole in cases of severe transverse lesions of the cord, and which I have called the "reduced flexor response," is a unisegmental reflex involving the first sacral segment only, and that when the physiological vitality of the lumbar enlargement is much reduced by isolation from the higher nervous system the only reflex response that can be obtained is a unisegmental reflex. My observations incline me to support strongly Colonel Gordon Holmes's theory. I have repeatedly noticed, in a case where some recovery is occurring and where the reduced flexor response is changing to the extensor response, that a minimal stimulus will produce flexion of the toes and a more severe stimulus will result in extension of the toes, or that there is first flexion and subsequent extension of the toes, but never the reverse. That is to say, the threshold for the unisegmental reflex is lower as one would expect.

Another most important point that the experience of this war has brought out is that the influence of the higher nervous system upon the reflex action and muscle tone of the spinal cord is strictly homolateral so far as the cord is concerned. That is to say, that a total unilateral lesion of the cord produces complete flaccidity with loss of knee- and ankle-jerk and reduction of superficial reflex upon the side of the lesion. This will explain those cases in which we meet with an extensor response upon one side and a reduced flexor response upon the other, in that one has a transverse lesion more complete upon one side than upon the other.

Contracture is a phenomenon which is intimately associated with the condition of reflex action. In these paraplegic cases with which we are dealing there are three conditions of contracture of the feet: 1. The dropped foot with retracted toes. This is the ordinary pes cavus of spastic states—the crystallisation of the extensor response. 2. The retracted foot with retracted toes. The calcaneus position is often extreme. The ankle-jerk is always lost and the anterior tibial-jerk marked. An extensor plantar reflex is always present. 3. The dropped foot with dropped toes, the position being similar to that of peripheral neuritis. The plantar reflex is either absent or there is a reduced flexor response.

I have observed in several cases the dropped foot with dropped toes gradually change into the spastic pes cavus with a change of the plantar reflex from the reduced flexor to the extensor type in cases where some improvement has taken place, and therefore I consider that the dropped foot with dropped toes indicates a more complete transverse lesion and that it is produced by a relatively greater muscular tone in the flexors of the toes than elsewhere, and that it is associated with the reduced flexor response just as the pes cavus is associated with the extensor response in less severe transverse lesions.

The calcaneus position with retracted toes is a very remarkable phenomenon. It has been persistent in those cases in which I have met with it, and has been always associated with loss of knee- and ankle-jerk and increase of anterior tibial and hamstring jerks. The extensor response and active withdrawal reflex have always been present. I have not examined such a case pathologically, but in one such case which Colonel Armour explored for me the chief lesion seemed to be a division of the ventral half of the dorsal cord.

I have carefully examined the electrical excitability of the calf muscles and of the anterior tibial muscles in extreme cases of the equinus and calcaneus positions, and have found that there is no difference in the faradic excitability of these muscle groups, thus proving that these positions of feet and toes are not due to any secondary lesions of the cauda equina or lumbo-sacral enlargement.

I have met with one curious reflex phenomenon in the leg in a way comparable to the curious reflex which Colonel Gordon Holmes has observed in the arm in a case of cervical lesion. My case was one of a mid-dorsal lesion, total upon the right side of the cord and severe upon the left. The right leg was completely flaccid and the only sign of reflex action present was that on stimulating the sole, after a latent period of four seconds or more, a feeble flexion and adduction of the thigh occurred. This reflex was easily tired out, and was only obtainable on gentle stimulation of the sole.

The physical signs obtaining in the lower limbs in transverse lesions of the cord seem to be the same whatever the level of the lesion above the lumbar enlargement.

There is one question which I would like to put to each of the speakers who follow me: What is the ultimate condition of the paralysed region in cases of total transverse lesion of the cord which are long survived? My own suggestion is that the slow process of physiological deterioration which we call "isolation dystrophy" may reach such a point that no signs of activity of the lumbar enlargement remain.

To the usual types of paraplegia resulting from lesions of the spinal cord and representing different degrees of isolation of the distal segment—namely, "paralysis in extension" and "paralysis in flexion"—I think that we might speak of a third type—that of complete flaccid paralysis. For it is from this stage of complete flaccid paralysis that the other types successively develop when improvement is occurring, and to this type they successively return when there is an increasing lesion or from long-standing isolation of the distal segment. There is, of course, no sharp separation between these types; they merge into one another gradually.

Distinction between Root Lesions and Central Lesions.

The diagnosis between lesions of the roots and lesions of the central grey matter is sometimes impossible, as, for example, when a lesion of either of these structures is complete. It is sometimes quite simple when a single root or so is damaged and there is characteristic sensory and motor loss in the area of distribution of the damaged root. In many cases, however, the diagnosis is far from a simple matter, and in some of these both lesions may exist together. The following points may be useful in the diagnosis: 1. In the cervical region extensive root lesions are only met with when there is severe injury of the bones, especially of the transverse processes and spines, and these are recognisable by deformity, swelling and œdema, and radiography in the absence of these signs, an atrophic palsy of the arms is probably the result of a central lesion, if it is extensive. 2. In central lesions the upper limit of the sensory loss is a line more or less transverse to the axis of the limb—that is to say, the sensory loss is of the "glove" or "stocking" pattern, in contrast to the more or less longitudinal limitation which obtains in root lesions. 3. In the cervical region a relative escape of the long columns or early signs of recovery in these with severe paralysis of the upper limbs is in favour of a root lesion, and may suggest the correct diagnosis at an early stage. 4. In the lumbo-sacral region the most certain indication is the level of the wound of the spine if this can be determined with certainty.

Disturbances of Sensibility.

The chief points of interest in this connexion are the paths taken by the sensory fibres in their spinal course, the sensory loss resulting from unilateral lesions, and the explanation of remote pains. The usually accepted paths of sensation in the spinal cord are as follows: 1. The path for touch is a double one, in the homolateral dorsal column and in the crossed lateral column. 2. Pain, heat, and cold are conveyed by separate fibres in the crossed ventrolateral column. 3. Sense of position, of passive movement, of vibration and recognition of form and of the compass points are conveyed in the homolateral dorsal column. The crossing of the sensory fibres in the cord occupies one to two segments in the lower dorsal region, but increasingly more segments as the cord is ascended, so that in the cervical region some five segments are occupied by the crossing. There is no crossing below the last dorsal segment. The path for painful and thermal stimuli crosses more rapidly than does touch. Consequently a unilateral lesion of the cord does not produce a Brown-Séquard syndrome when the lesion is at the level of the first lumbar segment or below this.

The symptoms of the unilateral lesion are that there is motor paralysis, loss of sense of position and of passive movement and of appreciation of vibration, form, and compasses upon the same side below the lesion, and loss of pain, heat, and cold upon the opposite side. The bilateral loss in the region of the lesion from the involvement of both right and left crossing fibres is narrower for pain and temperature than for touch. This bilateral loss is much narrower in the dorsal than in the cervical regions on account of the increasing obliquity of the crossing fibres. My observations have been in accord with the above scheme with one exception. In the majority of my cases of unilateral lesion of the cord the vibration sense has been lost or most affected upon the opposite side, and this has obtained both in severe and in slight lesions. I must admit that I have no pathological evidence in such a case.

Remote pains are very obstinate in some cases. Their mode of origin is obscure. Obviously, they are only met with in those cases where the sensory conducting tracts are relatively intact. The usual symptom-complex that I have met with is that there is a transverse lesion in the dorsal region with good recovery of sensibility and some recovery of power in the legs. There is considerable rigidity of the legs and phasic flexor spasms are invariably present, and there is more sphincter trouble present than the condition of recovery of motion and sensation would lead one to expect. There are three kinds of pain: dull persistent pain, sharp lancinating pains, and cramp. They are said always to disappear if the patient recovers. My experience is that they certainly persist if he does not recover.

There are three possible explanations of these pains: 1. That they may be caused by irritation of the sensory tracts in the region of the lesion. 2. That they may be caused by meningeal adhesions and matting of the cauda equina by the organisation of intrathecal extravasation of blood. 3. That they may be the result of the muscular rigidity and flexor spasms. Colonel Gordon Holmes is in support of the first of these causes, since in some cases the pain is distributed from the lesion downwards to the feet. The similarity of these pains to those which obtain in conditions of chronic spinal meningitis suggests that meningeal adhesions and

irritation of the roots are present in some of the cases. The fact that they disappear as recovery advances and persist if there is no further recovery points to the condition of local muscular spasm as being the chief cause in some of the cases.

RARE SYMPTOMS.

Among the rare symptoms which have been described, hypothermia and anuria in cases of cervical lesion and vomiting in mid-dorsal lesions have not come under my observation. These are early symptoms and are either rapidly fatal or they do not persist, so that we do not see them in the later stages. Pyrexia and tachycardia in cervical cases have both come under my notice, as has also polyuria in dorsal cases. Herpes zoster from injury to the root ganglia is necessarily an early symptom and has not occurred in any of my cases. Neither have I observed anything approaching the remarkable rhythmic movements which have occurred early, in so large a proportion of Colonel Holmes's cases of lesions in the upper lumbar region. I have had one remarkable case of cervical shivering.

CASE 9.—In this patient, who came under my observation within a week of his injury, the cervical laminæ were smashed in upon the cervical enlargement and there was total paralysis of all the limbs, the arms being flaccid evidently from a central lesion, but the legs were extended and spastic. Laminectomy was performed but no improvement took place. The legs slowly became flaccid. Cystitis developed and death ensued in ten weeks. The shivering involved all the muscles above the lesion; it was not apparent during the first few weeks, but it developed insidiously and became intense as the patient went down hill. For a time it was almost continuous and was a most distressing symptom. It was accompanied by the most profuse sweating of the head and neck and by marked signs of splanchnic palsy, abdominal distension, and low blood pressure.

Cervical shivering has been met with in lesions of the lower cervical and the upper three dorsal segments only and the lesions in all the cases have been severe.

PROGNOSTIC INDICATIONS.

In nearly all the cases the initial clinical picture is that of a total lesion of the cord, and in the early stages for prognostic indications as to how much of the transverse lesion is anatomical and how much physiological we must look to the condition of the reflexes. The early reappearance of the plantar reflex if lost at first and the change from the flexor to the extensor type soon after the seventh day, or the presence of an extensor response earlier than this, are certain indications that the lesion is partial and that some recovery will occur. Persistent loss of the plantar reflex and long-lasting flexor response are indications that the lesion is severe and that useful recovery is highly improbable. Early return of the knee-jerk and of the ankle-jerk is of good prognostic import. Even in the less severe cases the knee- and ankle-jerks do not return before the fourth day, and their reappearance before this date gives hope that complete recovery may occur. Colonel Gordon Holmes is of opinion that the presence of an extensor response is a certain indication that the lesion is incomplete. These remarks apply to each leg individually. The condition of the reflexes on one side has no bearing as to the recovery of the opposite limb. The further prognostic indications are simple. They depend upon the date of return and the rapidity of return of sphincter control, of sensibility, and of motor power. Early return of sphincter control is one of the best of signs. In two cases where recovery has been complete, and in two other cases where recovery has been nearly complete, some sphincter control returned within a week of the injury.

THE DISSOCIATION OF CUTANEOUS SENSATIONS IN INJURIES TO PERIPHERAL NERVES.

BY DONALD E. CORE, M.D. MANCH., M.R.C.P. LOND.,

CAPTAIN, R.A.M.C. (T.F.); HONORARY PHYSICIAN, THE ANCOATS HOSPITAL, MANCHESTER.

DURING the past eighteen months a series of observations have been carried out on the patients of the 2nd Western General Hospital for the purpose of comparing the relationship to each other of the areas of anæsthesia to different forms of cutaneous stimuli resulting from injuries to the peripheral nerves. A preliminary communication will be of interest. It has been found that the comparison of the area of sensory loss to the touch of a small brush with that to the prick of a sharp steel needle gives valuable information as regards the kind of injury from which the affected nerve is suffering.

In testing cutaneous sensation with different forms of stimuli it is not common to find an exact correspondence of the respective areas of sensory loss, and this is especially true for the types of sensation represented by light brushing of the skin and gentle pricking. The kind of brush used throughout in these observations has been that sold by Messrs. Winsor and Newton under the name of "crow sable." This method is rough when compared with the use of von Frey's hair æsthesiometer, yet such a brush, when suitably mounted in a metal handle, is capable of producing a very delicate form of skin stimulus. The other form, gentle pricking of the skin with a sharp steel needle, was employed in such a way that the pressure used was just enough to evoke a feeling of pain when a corresponding area of skin on the opposite limb was touched in the same way.

Nerve injuries may be complete or incomplete and the latter group comprises a number of injuries, varying from partial severing of the nerve with more or less implication of the remaining fibres in the resulting fibrous tissue, to pure compression without any anatomical division. Although it is easy in most cases to classify a nerve injury as "severe" or "slight," it is not easy in my experience to make quite sure that the lesion is or is not complete in cases of the first of these groups, from the extent and intensity of the symptoms alone. Often enough, motor and sensory loss that appeared from their severity to indicate a completely divided nerve have been shown later to have been due to an incomplete division. The motor symptoms and the sensory loss are not in themselves enough to settle the question, whereas a comparison of the areas of anæsthesia to the two forms of stimuli mentioned above, in the majority of cases, is.

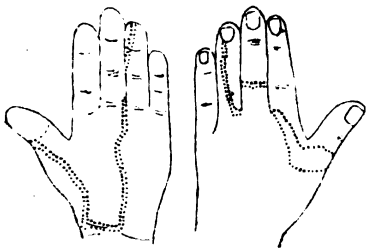
The study of complete nerve injuries is best carried out in post-operative cases, in which the completeness of the division is certain. For access to this class of case I am indebted to Lieutenant-Colonel J. W. Smith, Lieutenant-Colonel W. Thorburn, Major J. Howson Ray, and Captain E. D. Telford.

Complete Division of a Nerve.

When a nerve trunk has been completely divided the following condition is found in the field of its distribution: a centrally situated area of profound sensory loss and a peripheral zone of loss to the more delicate forms of stimuli. If this peripheral zone be examined with the brush and needle in the

manner described above it will be found that the loss of sensation to brush is more extensive than that to the needle. Figs. 1 and 2 are examples of such cases (Fig. 1) being from a young officer whose median nerve had been resected by Lieutenant-Colonel Thorburn, and Fig. 2 from a case of ulnar nerve resection performed by Lieutenant-Colonel Smith.

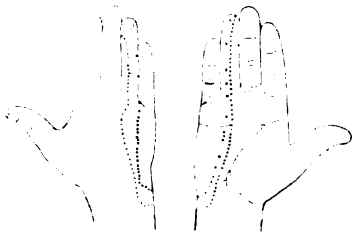
Compression of a Nerve.



In cases of pure compression without any anatomical division of the nerve fibres the reverse holds, and there is a dissociation of sensation in which the loss to needle-point is greater than that to brush. In the majority of cases this is very definite indeed, the patient under examination saying that in the intermediate area he cannot feel the pain of the prick, although he can feel the touch of the needle. The following is taken from a very instructive case of this kind. The patient was a private who complained of loss of sensation and dryness of the skin over the inner side of the forearm on the left side with weakness of the small muscles of the left hand. There was no wound to account for his symptoms and a radiograph showed the presence of a cervical rib on the *right* side and something that was described as an abnormal ossification about the first rib on the left side, the side of the anæsthesia. The dissociation of sensation in this anæsthetic area was: Loss to needle-point more extensive than that to brush. At the operation, which was performed by Captain Telford, there was found a normal first rib on the left side, exerting compression on the branch of the first dorsal root passing to the brachial plexus; this contribution from the first dorsal was abnormally big. Relief of the compression was followed the day after by sweating in the anæsthetic area, a condition that had been absent for months. In other words, this dissociation of sensation, loss to needle-point more extensive than that to brush, was due to compression of the nerve fibres in this case, and from other patients that I have seen I have come to the conclusion that this form of dissociation is characteristic of compression and is against division of the nerve, certainly against complete division.

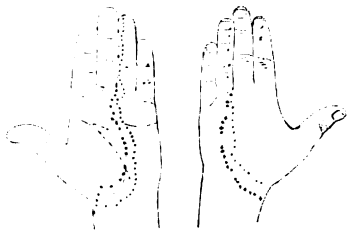
In the two types of cases described above complete division and pure compression, the marks made in mapping out the two areas of sensory loss will be found to remain equidistant from each other, but a number of cases are met with in which this equidistance is not maintained. Two such variations are commonly met with.

1. The types of dissociation are mixed; for part of the area of anæsthesia there is the dissociation of complete division, and for the remainder that of compression. This leads to a "lateral displacement" of the two areas of sensory loss. In some of these cases this relationship is due to the implication of two nerves in the wound, innervating adjacent areas of skin; one is divided and one compressed, and the loss to brush falls without and within that to needle-point respectively. Fig. 3 is a case of this description. The wound was a severe one on the inner side of the left arm just above the elbow; the humerus had been injured and the median and radial nerves involved. The median area showed the dissociation of complete division, the small muscles of the thenar eminence were paralysed and wasted, and the reaction of degeneration was present. The radial nerve area showed a dissociation of compression; the pressure of a blunted object was appreciated.



In other cases of this type the anæsthesia indicates the injury of one nerve only, and yet the dissociation is of this mixed type. Further investigation is required for these cases, but I am strongly of the opinion that they are due to a partial division of the nerve with compression of the remaining undivided fibres. This view is strengthened after reading the paper by Captain Wilfred Harris in THE LANCET of Nov. 13th, 1915, p. 1073, where the writer describes a case in which he found reason to believe that in the median nerve there was a separation of fibres destined to innervate the dorsum of the fingers from those running to the palmar aspect of the hand; and that this separation took place early in the nerve trunk. If this separation exists as a rule in nerve trunks, then it is quite probable that an incomplete division of the nerve would lead to the form of dissociation under consideration.

FIG. 1.



The dots (outer line) represent the limits of anæsthesia to brush touch; the crosses the limits of that to needle-prick.

FIG. 2.

The dots and crosses have the same significance as in Fig. 1.

FIG. 3.

The dots and crosses have the same significance as in the preceding figures.

2. In this type the limits of the areas of sensory loss to brush and needle-point respectively approach and recede, so that they show an undulating or wavy relationship to each other. For the most part the dissociation is that of compression, the needle-point loss falling without the brush loss; in some cases, however, the limiting edges of the two sensory losses frequently cross each other. In yet another variety of this type the edges show a tendency to coincide for a considerable part of their course.

It is not quite easy to assign the true cause to these forms of dissociation, other than to say that they are not due to complete division nor to pure compression. They are found most often, I think, in cases that are "hanging fire" for some cause or other, and the outlook in such cases is not good.

Summarising these results, then, I would lay emphasis on the statement that it is possible in the great majority of cases to diagnose the condition of the affected nerve from the dissociation of cutaneous sensations met with.

In complete division the loss to brush is more extensive than that to needle-point (cutaneous pain).

In pure compression the loss to brush is less extensive than that to needle-point.

A dissociation characteristic of complete division associated with one significant of compression is occasionally met with. This leads to a "lateral displacement" of the two areas of sensory loss; it is met with when more than one nerve is injured, and when the nerves involved supply contiguous areas of the skin. It indicates the complete division of one of these and the compression of the other. When such a dissociation is met with in the territory of one nerve it is possible that it is the result of partial division of the nerve with compression of the undivided fibres.

An undulating form of dissociation, where the limiting edges of the two areas of sensory loss approach and recede or constantly cross each other, is met with in cases that are at a standstill. No satisfactory explanation has as yet been arrived at for this type.

In certain areas there is no dissociation; the two areas of sensory loss coincide. I have not found this common except in lesions of the external popliteal nerve.

In the course of the above investigation several cases were seen that differed from the majority of cases of nerve injury in that pain was a prominent symptom. In many of the cases dealt with a certain amount of discomfort was present, but in those under discussion now the pain has certain characteristics that put them into a class by themselves. Such pain is intense; it is associated with extreme tenderness over the affected parts: it is badly localised. The patient does not give any precise description of its whereabouts, but can only say vaguely that it is in the palm of the hand or the sole of the foot, as the case may be. The pain is of a burning, tingling character and reacts variably to hot and cold applications. My experience of these cases is that cold is preferred in the majority rather than heat. The condition is associated with incomplete injuries of the nerve affected, and the nerves most commonly affected in this way are the median and the great sciatic.

If the history of a case of this kind is asked for, it will generally be found that the pain and tenderness did not appear for some little time after the wound, and the sequence of symptoms during the course of the case is instructive. The sensory loss increases in extent and intensity during the period of the pain; when the pain subsides, as it does in the course of time, what at the time of the injury was a comparatively slight sensory loss, at the time of subsidence is that of a practically complete nerve division, the type of dissociation most frequently met with being the wavy variety. Trophic changes are usually prominent in cases of this kind.

If a part of the nerve affected be excised at the site of the injury, there is found a diffuse intraneural fibrosis. This fibrosis is distinct from the perineural fibrosis or implication of the trunk in scar tissue, and is to be looked upon as the cause of the pain and tenderness. It is a progressive condition, and ultimately leads to the loss of conductivity of the nerve affected, in the absence of suitable treatment. Intraneural fibrosis of this kind does not occur in cases of primary complete division; it is liable to occur in nerves that have been partially divided and that are associated for the greater part of their length with soft tissues—nerves that are associated with bones will be compressed too rapidly in the majority of cases for the intraneural fibrosis to develop. The median and sciatic nerves are thus specially prone to the condition.

The dissociation of certain of the cutaneous sensations as a result of injuries to nerves, whether due to complete division or to compression, opens up many points of interest, notably the cause of the different degrees of vulnerability of nerve fibres and the bearing of this on the dissociations that are to be found in conditions other than peripheral nerve injuries. These points, however, are out of place in a communication of this kind; they will be dealt with in a future paper.

In these investigations I have been associated throughout with Dr. J. S. B. Stopford, of the Anatomy Department of the University of Manchester. The existence of the dissociations described above was recognised early, and we decided to devote our attention to their significance. The division of work was such that Dr. Stopford saw for the most part the post-operative cases and I saw those that had not been operated upon; on comparing our findings Dr. Stopford suggested that this might account for the two forms of dissociation described above. Every case that we have examined since then has strengthed our conviction that this is the true explanation of these two forms of dissociation. The bearing of our observations on the subject of treatment is being dealt with by Dr. Stopford in a paper which I am informed is about to be published.[1]

GUNSHOT INJURIES OF THE PERIPHERAL NERVES: THE SYNDROME OF COMPRESSION.

BY JOHN S. B. STOPFORD, M.D. MANCH.,
LECTURER IN ANATOMY, UNIVERSITY OF MANCHESTER.

THE numerous examples of injury to the peripheral nerves in our military hospitals probably provide more problems than any other class of case, and the controversies about the advisability of surgical interference are still maintained in this and other countries. Contact with these cases makes it apparent that critical observations and further investigations are necessary in order to obtain the highest percentage of good functional results with the shortest periods of inactivity.

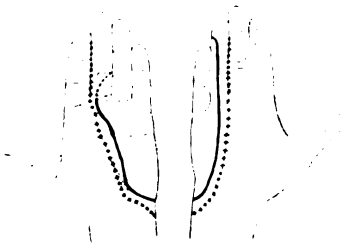
At the outset most cases exhibit a complete interruption of conduction in the affected nerve below the site of the injury, but even at this time the anatomical diagnosis may be obscured either by superadded functional manifestations (especially in lesions of the clavicular region) or damage to one or more other nerves. The latter complication produces greater difficulty later, as, owing to the frequent variation in severity of the injury inflicted upon the individual nerves, it is not unusual to get early partial recovery in one which causes an irregular anatomical distribution of the motor and sensory symptoms.

Owing to the profound initial symptoms obscuring the extent and character of the injury, and the risk of sepsis, it is universally considered advisable to withhold operative measures until the wounds are soundly healed and the nerve has had a reasonable opportunity of demonstrating signs of recovery. There is considerable divergence of opinion as to the length of this period because it is impossible to enunciate any hard-and-fast rule. Each case ought to be decided on the results of careful regular clinical examinations, and it is hoped that some of

[1] The paper referred to commences on this page.

the points raised in this paper may be helpful at this stage. During the important period of observation the paralysed muscles must be fully and constantly relaxed by splints, and daily massage and passive movements practised in order to encourage recovery and prevent contractures.

From the observation (on behalf of the Medical Research Committee) of upwards of 90 cases in the hospitals of the 2nd Western Command, it is suggested that the following factors must be considered as influencing the prognosis and consequently the treatment.



1. The extent, character, and distance from the periphery of the injury. Extensive damage to the surrounding structures increases the formation of scar tissue, which by its contraction is liable to strangle the nerve. Irregular missiles, as shell casing, tend to lacerate the nerves themselves more than bullets. A nerve which is in a state of tension at the time of the reception of the injury is more likely to be torn than one which is lying slack, and consequently the position of the limb influences slightly the predisposition to laceration. It is well known that peripheral injuries of nerves have a better prognosis than more central ones in the region of the nerve roots.

2. Such complications as fracture and sepsis obviously add to the gravity of the prognosis. They both magnify the risk of secondary implication of the nerve in either callus or fibrous tissue.

3. The treatment before the case comes under observation is also important, as failure to relax the paralysed muscles during the early stages appears to be a very potent cause of delay in recovery.

4. The amount of cicatricial tissue formed around the nerve. Excessive fibrosis and the frequency of incomplete division constitute, to a considerable extent, the differences between war injuries of nerves and those encountered in civil practice. The effect of fibrous constriction during healing is most significant in the study of these cases, and its influence upon prognosis and treatment cannot easily be over-emphasised.

FIG. 1.

Analgesia (crosses) and anæsthesia (line) in Case 1 before operation.

FIG. 2.

Analgesia and anæsthesia in Case 1 after resection.

For convenience of discussion the clinical progress, in a large proportion of nerve injuries, may be said to follow one of the four following courses (although, it must be understood, it is not possible to include a few cases exhibiting several complications in such a graphic manner).

(*a*) Improvement seen in the sensory manifestations within a few weeks, followed by restoration of tone and voluntary contraction in the paralysed muscles. This is succeeded by a steady increase in power until there is a complete recovery within four to eight months. The cases following this course are probably examples of physiological division, the missile having passed close to the nerve without dividing any fibres and the wound healing without any compression of the nerve.

(*b*) No improvement of any form even after four to six months. All of these cases are clinically examples of complete anatomical division, and surgical means alone can procure any recovery.

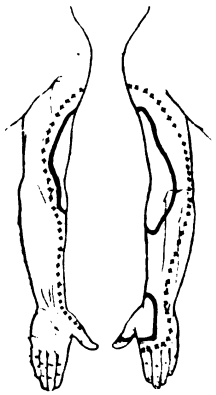
In these two diverse groups the treatment is obvious, but in the next considerable difficulties are encountered.

(*c*) Fairly rapid improvement in the sensory or motor symptoms, or both, up to a point when further progress becomes more tardy but very slowly continues. These are possibly instances of incomplete anatomical division, but the divided fibres regenerate because they are in good apposition, and there is a minimal amount of cicatricial tissue. Surgery cannot accelerate the recovery of this group and the essential point is to differentiate it from the succeeding one. As Sherren[1] has shown, in cases of incomplete division the recovery of epicritic and protopathic sensibility is simultaneous.

(*d*) Improvement, which abruptly ceases or is followed by a relapse. This is an important group and contains a considerable number of cases. The relapse, as may be anticipated, is almost invariably due to compression of the nerve by fibrous tissue or callus.

In the cases of relapse or sudden cessation of all recovery the nerve is found on exposure to be compressed by fibrous tissue, or to contain a fibroma or extensive intraneural scar. The progress or regeneration is interrupted by the excessive formation of fibrous tissue, which usually necessitates neurolysis or excision of the fibroma with suture of the divided fibres, and therefore it is of the utmost importance to be able to diagnose this class of case as soon as possible from those in the previous group, where recovery will generally occur without surgical intervention.

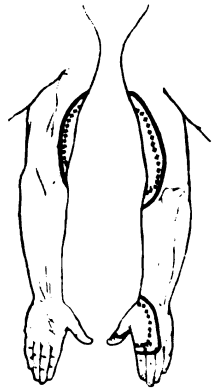
From my own experience it seems possible to recognise the presence of compression of a nerve in most cases by means of the simplest clinical tests for the cutaneous sensibility to "light touch" and "pain" in its sensory distribution. The following cases illustrate this possibility.



CASE 1.—Private —— received on May 9th, 1915, a gunshot injury on the inner side of the left arm about 2 inches above the internal condyle of the humerus. He was first seen by me on Sept. 15th, when there was a complete paralysis of all the muscles supplied by the ulnar nerve and sensory symptoms indicated in Fig. 1. It will be immediately noticed that the analgesia was more extensive than the anæsthesia (lightest touch). He had suffered from a burning pain in the palm of the hand for the previous two months, but this was diminishing in intensity and totally disappeared about the end of September. No improvement occurred and he was operated on by Captain H. Buck on Nov. 12th. At the operation the nerve was found to be firmly adherent to the inner head of triceps; its most internal fibres had been divided and a fibroma had developed between their lacerated ends. A few apparently normal fibres were to be seen on the outer side. About one inch of the nerve with the fibroma was resected and the divided ends sutured and protected with a covering of fat. Microscopic examination of the excised piece showed three bundles of nerve fibres intact, but the rest had been strangled by the dense fibrous tissue. Sensation was tested six days after the operation, and it was found that the analgesia was now less extensive than the anæsthesia as shown in Fig. 2 (the dissociation is the reverse of that seen in Fig. 1, before operation).

CASE 2.—Private —— received on August 8th a shell injury of the left shoulder, the piece entering just below the spine of the scapula and emerging through the inner third

[1] J. Sherren; Injuries of Nerves and their Treatment.

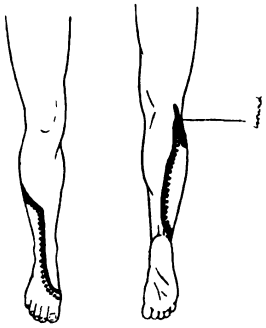


of the clavicle, causing a comminuted fracture of that bone. There was immediate paralysis of the whole arm. In about four weeks he was able to flex the fingers slightly, and a little later succeeded in slowly flexing the elbow. About this time he suffered a good deal from a severe pain along the outer side of the arm, and this was found to be more intense when the limb was warm. When examined on Nov. 22nd there was paralysis of the clavicular portion of the pectoralis major, deltoid and extensors of the wrist, thumb and fingers, with paresis of the triceps. The objective sensory manifestations are demonstrated by Fig. 3, in which

FIG. 3.

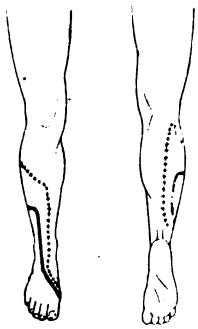
Analgesia and anæsthesia in Case 2 before neurolysis.

FIG. 4.



Analgesia and anæsthesia in Case 2 a fortnight after neurolysis.

it will be seen the analgesia is much more extensive than the anæsthesia. At the operation, performed by Captain Buck, the posterior cord of the brachial plexus was found to be strongly adherent to the posterior aspect of the clavicle in the region of the fracture. No evidence could be found of any division of nerve fibres. When examined two weeks after the operation it was found that the type of dissociation in the sensory symptoms had been reversed. (Fig. 4.) A fortnight later there was scarcely any anæsthesia or analgesia, and slight voluntary contraction of the deltoid was seen. Improvement is continuing.

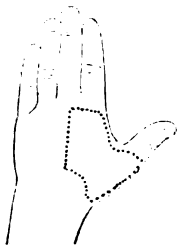


CASE 3.—Private —— received a gunshot wound of the right leg, which caused an extensive linear wound along the inner border of the biceps tendon, extending about 4½ inches proximally from the head of the fibula. The wound became very septic and took nearly three months to heal. When examined before the wound had healed he complained of severe dragging pain in the foot and had

FIG. 5.

Analgesia and anæsthesia in Case 3 before the wound had healed.

FIG. 6.



Analgesia and anæsthesia in Case 3 after the relapse.

paralysis of the anterior tibial and peroneal muscles. On testing the sensibility it was found that the losses to "light touch" and "pain" respectively were almost coterminous (Fig. 5), the condition usually found in complete division of the external popliteal nerve. During the next few weeks there was a gradual recession of the proximal limit of the anæsthetic and analgesic areas and some voluntary contraction in the extensor longus hallucis and extensor longus digitorum, but this was only maintained until about a fortnight after the wound had healed when a relapse occurred. The pain ceased, there was no longer any voluntary contraction in the anterior tibial muscle and the analgesic area was found to be very considerably greater than the area of anæsthesia (Fig. 6), which was not quite so extensive as at the outset. At the operation Captain E. D. Telford found the external popliteal nerve incompletely divided and embedded in an enormous mass of hard fibrous tissue and it was found necessary to resect a portion of the nerve. Unfortunately, I was unable to again examine this case after the operation owing to its transfer to a distant hospital.

The following two cases show more clearly the development and effect of compression on a peripheral nerve.

CASE 4.—Rifleman —— received on June 25th a shell wound on the outer side of the left biceps tendon and in front of the external condyle of the humerus. It was an uncomplicated flesh wound, and at first there were no manifestations of any nerve injury. The wound rapidly healed, and soon after it became sound he experienced difficulty in raising his wrist. This became gradually worse, until he was quite unable to extend his wrist, thumb, or fingers. When examined at this time he had complete flaccid paralysis, with wasting of all the muscles supplied by the posterior interosseous nerve, and complained of pain in the thumb and dorsum of the hand, but there were no objective sensory symptoms. In a few weeks the pain subsided and an analgesia, whose distribution is demonstrated in Fig. 7, appeared. There was no loss to light touch. This condition persisted for one month, during which time the paralysed muscles were constantly relaxed on a splint and regularly massaged. At the end of this time the extensors of the wrist exhibited signs of tone, and later a little voluntary contraction. This was succeeded by a gradual reduction in the area of analgesia, and now there are no sensory manifestations and full power has practically returned in the affected muscles.

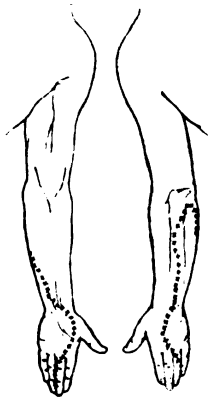


FIG. 7.

Analgesia (no anæsthesia) in Case 4.

CASE 5.—Private —— whilst in the Dardanelles noticed that his left hand began to lose its power after about half an hour's trench digging or rapid fire. The weakness rapidly increased, and he also observed wasting of the hand. In addition he suffered from a shooting pain down the ulnar border of the forearm and hand which was induced by carrying anything or wearing his heavy overcoat, or sometimes even by his braces. On examination there was paresis with atrophy of all the small muscles of the hand, and also slight weakness of the flexors of the fingers, especially on the ulnar side. The affected hand was dry, cold, and slightly cyanosed. The only objective sensory symptom was analgesia over part of the distribution of the inner cord of the brachial plexus. (Fig. 8.) Epicritic sensibility, even to the compass test, was unaffected throughout. An X ray examination showed a cervical rib on the right side, but none on the affected side. At the operation, performed by Captain Telford, a very large contribution from the first dorsal root was found ascending in a deep groove on the inner border of the first rib to join the last cervical nerve. There was no compression of the subclavian artery. The portion of rib obviously compressing the first dorsal root was excised. On the following day (24 hours after the operation) the hand was warm and moist, and the analgesia had completely disappeared. The capillary circulation was still a little sluggish, but there was no cyanosis, and the man volunteered the information that "during the night he had felt the blood pumping through his left hand for the first time as long as he could remember." (A full report of this interesting case will be published subsequently in a separate paper.)

FIG. 8.

Analgesia (no anæsthesia) in Case 5.

All these cases exhibit a dissociated type of sensory disturbance; in each the area in which there is a loss of sensibility to pain (tested by pinprick) is greater than that in which the loss to light touch (tested by camel hair brush) occurs, a syndrome which is the reverse of that enunciated by Head, Rivers, and Sherren[2] for injuries of peripheral nerves. I have discovered this type of

[2] H. Head, W. H. R. Rivers, and J. Sherren: Brain, vol. xxviii., 1905.

dissociation in 15 additional cases, but have failed to find it in the examination of recent injuries. In every case where it was found it developed after the wound had healed. In this connexion it is interesting to note that my attention was first directed to this dissociation by Captain D. E. Core, who was at the time examining old cases, whereas I was seeing only the recent ones, and it was only later when I began to see it develop that I realised its significance. All the examples of this dissociation which have come to operation show one pathological condition in common—namely, compression of a nerve which is undivided or incompletely divided.

In the first three cases described the compression was observed on exposure of the nerve. In the first the dissociation was reversed by complete division, in the second by neurolysis, whilst in the third unfortunately I was unable to make an examination after the operation. In the fourth case the position and character of the injury and the very late onset of the nervous symptoms indicate compression by the contraction of the scar. The manifestations were not so profound as in the former cases, and recovery occurred without neurolysis. The fifth case—compression of the first dorsal contribution, to a probably post-fixed brachial plexus, by a normal first rib—proves still more clearly the effect of pressure and the rapid relief to be obtained in early cases by its removal.

These observations seem to show that the first signs of compression are manifested by loss of conduction in the motor fibres and severe pain, which are succeeded by analgesia and diminution (later disappearance) of the subjective pain, and later tactile anæsthesia, which is never so widespread as the analgesia. Any reference to thermal anæsthesia is here omitted as it is not so conveniently tested clinically as "pain" and "light touch," which appear to give the necessary practical information. The simple examination required enhances the clinical value of this sign. This form of dissociation can be rapidly tested, and the only conditions with which it can possibly be confused are complete division of posterior roots and perhaps syringomyelia; but these errors may easily be avoided.

It is unnecessary to account for the frequency of the signs of compression in military cases after Bowlby's[3] recent description of the way in which all bullet or shell fragments, moving at immense speed, not only shatter the structures in the line of their flight, but by their divulsive force shatter and lacerate the surrounding tissues for remarkable distances in all directions. This form of dissociation is not only of importance in diagnosing compression, but also useful in proving the relief of compression after neurolysis.

It is not intended here to refer to the theoretical significance of this phenomenon, but it is of interest to mention the hypothesis, supported by Ranson's[4] recent work, that the afferent fibres conducting protopathic sensibility are non-medullated.

[4] S. W. Ranson: Unmyelinated Nerve Fibres as Conductors of Protopathic Sensation, Brain, vol. xxxviii., 1916.

Dr. F. T. Underhill, medical health officer of Vancouver, in presenting his annual report for 1915, lays chief stress on the need for thorough inspection of all foods and their distribution, and the inspection of dairy-farms, milk- and other food-shops, and food-hawkers. He notes that after two or three years' steady work bakehouses are all free from vermin, and wrapped bread can be had from all bakers.

INVESTIGATIONS OF STRAINS OF TUBERCLE BACILLI DERIVED FROM SPUTUM.

BY A. STANLEY GRIFFITH, M.D. VICT.
(*For the Medical Research Committee.*)

IN May, 1914, I communicated to the *British Medical Journal*[1] the results to that date of investigations of strains of tubercle bacilli derived from the sputum of phthisical persons. Since then I have isolated and investigated a further series of cultures from sputum. These additional strains of tubercle bacilli were obtained in the course of experiments made in test of a simple method, mentioned in my last paper, of raising cultures directly from sputum by means of antiformin. I have also completed the investigation of four atypical sputum strains which were omitted from the report on the last series because their biological characters had not then been satisfactorily established. As my work on these lines is for the time being at an end (September, 1915), I propose in this paper to summarise the whole of my observations upon the types of tubercle bacilli in the sputum of consumptives. The total number of strains of tubercle bacilli isolated by me from sputum is 212. Of these, 29 were investigated for the Royal Commission on Tuberculosis,[2] 152 for the Grocers' Company, and the remainder (31) on behalf of the Medical Research Committee.

The subject-matters of this report will be dealt with in order as follows: (*a*) Outcome of my observations on the sputa of 31 additional cases of phthisis pulmonalis. (*b*) The biological characteristics of four atypical sputum strains from Series 2. (*c*) Analysis of the results obtained in examination of sputum from 212 cases of phthisis pulmonalis. (*d*) My further experience of antiformin as a means of eliminating from sputum and from tuberculous tissues all micro-organisms other than B. tuberculosis.

(*a*) *31 Additional Strains.*

Thirty-one new strains of tubercle bacilli have been raised from sputum. The patients from whom the sputum samples were derived varied in age from 17 to 53 years; 15 were under 25 and 3 were over 40. Of the patients 12 were females and 19 were males. I am indebted to Dr. W. M. Elliott, Ruchill Hospital, Glasgow, and Dr. J. W. Allan, Bellefield Sanatorium, Lanark, for specimens of sputum from 28 persons, and to Mr. P. C. Varrier-Jones, Cambridge, for the specimens from the other three.

A small quantity of each sputum sample was inoculated intraperitoneally into one guinea-pig. Of the 31 guinea-pigs so inoculated two died prematurely; the rest developed typical general tuberculosis. Direct cultures were sown from each sputum after treatment with antiformin, and in this way cultures of tubercle bacilli were isolated from 26 of the samples. From the remaining 5 samples, as well as from 8 which had yielded cultures direct, cultures were derived through the guinea-pig. The cultures have been tested as to their cultural characteristics only. Each of the strains has produced on bovine serum good growths with yellow pigment, and on glycerine agar, potato or broth the luxuriant creamy wrinkled layers which are characteristic of the human type of tubercle bacillus.

In order to ascertain whether or not a strain is capable of producing pigment on serum it is essential to use bovine serum which is of yellow colour when coagulated. The serum I have used for subcultures has, during the greater part of my work at Cambridge, been obtained from a single animal, a Shorthorn cow, which is kept at the farm for the sole purpose of supplying serum. Different batches of serum from this cow have varied in colour, when coagulated, from pale yellow to golden yellow, but all have favoured the production of pigment. On a golden yellow serum the human type of tubercle bacillus produces a rich yellow, often orange-yellow, pigment. With a less yellow serum the colour of the pigment varies from light cream to yellow. On a colourless serum, such as is usually obtained from the calf, pig, goat, or horse, the growths of human tubercle bacilli are greyish or greyish-white and are not pigmented. Standard bovine cultures have never in my experience produced bright yellow pigment, even on a golden yellow serum. Yellow pigment in a serum culture is therefore a character of considerable differential value.

(*b*) *Four Atypical Strains.*

With the exception of the majority of strains derived from lupus and of a few mixed strains, all the strains of tubercle bacilli of human origin upon which I have previously reported have been readily classified as either of bovine or of human type. This classification has been based upon the characters of growth on artificial media and the virulence for certain species of animals, the rabbit being the standard test animal. The deviation from type observed in the majority of lupus tubercle bacilli has been in respect to virulence, the cultural characters of these strains having been those of either the human type or the bovine type of tubercle bacillus.

During my work on tuberculosis in Cambridge I have obtained now and again from various kinds of human tuberculosis strains of tubercle bacilli which have displayed another kind of anomaly. These strains have exhibited standard (mammalian) virulence, but have not corresponded to either of the two mammalian types of tubercle bacilli in respect to their cultural characters. Of this new variety of tubercle bacillus I have obtained four strains from sputum. The following is an account of the biological properties of each such strain, together with an abstract of clinical notes of the case in each instance. For the latter I am indebted to Sir Robert Philip and Dr. J. J. Perkins.

CASE 1.—A woman, aged 24, was admitted to Brompton Hospital in 1911. The upper and lower lobes of both lungs were affected. The duration of the lung trouble was stated to be about three years.

Bacteriological Investigation.—Sputum obtained in May, 1912, was muco-purulent and contained fairly numerous T.B.; majority of medium length, a few long and beaded. A culture was isolated direct. Subcultures on serum were luxuriant, and on a yellow bovine serum exhibited a rich yellow pigment. On glycerine serum growth was luxuriant, pigmented, more heaped up than on serum, parts being wrinkled and warty. On glycerine agar at the end of a month growth was partly grey and translucent and partly creamy-white and wrinkled. After three or four months' incubation the major part of the layer was creamy, wrinkled, and of moderate thickness, the rest being grey and like ground glass. Similar growths were obtained on several agar tubes, and they differed from those ordinarily produced by standard human tubercle bacilli in being less abundant, not so uniform, and slower in attaining the maximum. On glycerine potato the most usual result in upwards of 24 tests was the production of a thin grey layer in which secondary colonies appeared after from two to three months. On further incubation these colonies increased slowly in size, becoming very irregular and bizarre in shape, resembling those often produced by bovine tubercle bacilli on this medium. Occasionally the growths were greyish-yellow and granular, but not much raised. On one occasion a moist, whitish, finely wrinkled but not thick layer was produced. On glycerine broth the best growth obtained after many attempts was a moist, greyish-white, mottled, not thick pellicle covering two-thirds of the surface, the rest being covered by extremely delicate transparent film.

A rabbit inoculated subcutaneously with 35 mg. of culture was killed 124 days after inoculation. The necropsy showed a small local lesion, partial caseation of one scapular gland, and scattered miliary tubercles in the lungs. Two guinea-pigs inoculated subcutaneously (one partly intraperitoneally), each with 0·1 mg., died of typical tuberculosis in 47 and 149 days respectively.

CASE 2.—Sputum from a woman aged 23 was received in January, 1912. She was suffering from pulmonary tuberculosis and had a blood-stained muco-purulent expectoration containing numerous beaded T.B.

Bacteriological Investigation.—A culture was obtained direct from the sputum. Subcultures on serum and glycerine serum were identical with those of Case 1 strain. On glycerine agar growth was difficult to obtain, the majority of the tubes sown showing no visible growth after several months' incubation. On other agar tubes there was in the second month a definite but extremely thin filmy grey layer, around the margins of which, under low magnification, very minute discrete colonies could be seen. After further incubation, up to four months, secondary colonies were seen in the thin grey layer, but these were only just visible to the naked eye and were grey and filmy or greyish-white. After incubation up to six months the appearances were the same as after three and four months. On glycerine potato in the great majority of cases only a thin grey layer was produced after several months' incubation. In one tube numerous secondary colonies developed in the thin grey layer, but these remained minute. In another tube, after nine months' incubation, there was a thin, moist, greyish-white layer containing half-a-dozen creamy warty colonies up to a millet seed in size. On glycerine broth only a few filmy grey islands of growth have been obtained.

A rabbit inoculated subcutaneously with 45 mg. of culture and killed 124 days later showed a local lesion and moderately severe tuberculosis of the lungs only. Another rabbit inoculated subcutaneously with 10 mg. of culture and killed 97 days later also showed a local lesion and moderate tuberculosis of the lungs only. A culture from the lung of the latter rabbit resembled the original. Three guinea-pigs were inoculated, each with 0·1 mg. One, intraperitoneally inoculated, died in 27 days of typical subacute general tuberculosis. Of the two subcutaneously inoculated guinea-pigs one died in 61 days of general tuberculosis; the other died in 114 days of chronic general tuberculosis of fibroid type. Cultures from two of the guinea-pigs were identical in cultural character with the original.

CASE 3.—A woman, aged 31, was admitted to the Royal Victoria Hospital, Edinburgh, on March 20th, 1913, on account of cough, loss of appetite, and weakness. The duration of illness was stated to be six weeks. Personal and family history unimportant. On examination she showed bilateral pulmonary tuberculosis, more extensively involving right side, where there was evidence of vomication. There was marked constitutional disturbance. The patient died some time later in a home for incurables.

Bacteriological Investigation.—Thick muco-purulent sputum was received in November, 1913. It contained very numerous tubercle bacilli; many were long, curved, and beaded. A guinea-pig inoculated intraperitoneally with the sputum died in 32 days of typical general tuberculosis. A rabbit inoculated subcutaneously and killed 92 days later showed no more than a small local lesion and a caseous focus in one adjacent gland. Cultures were isolated directly from the sputum. Subcultures on serum and glycerine serum were luxuriant and pigmented like those of the strain from Case 1. On other media containing glycerine growths were very sparse and closely resembled those produced by the strain from Case 2. A rabbit inoculated subcutaneously with 15 mg. of the culture and killed 101 days after inoculation showed a small softened caseous lesion and three tubercles in the lungs only. A culture recovered from one of these tubercles resembled the orginal culture in cultural characteristics and in virulence for the rabbit.

CASE 4.—A woman, aged 38, was admitted to the Royal Victoria Hospital, Edinburgh, in August, 1913, on account of cough, breathlessness, &c. The duration of her illness was stated to be 14 months. Examination revealed extensive involvement of left lung and slighter involvement of right apex. Systemic disturbance marked. Sputum showed moderate numbers of T.B. during first five months' treatment; thereafter the examination was negative. The patient improved considerably under treatment, and on discharge there was diminution in the area involved and T.B. were no longer detected in the sputum.

Bacteriological Investigation.—A sample of the sputum received in November, 1913, was thick, viscid, and contained a moderate number of T.B., mainly long, curved, and beaded. A rabbit inoculated subcutaneously with a small amount of the sputum and killed 95 days later showed a local lesion, a dozen tubercles in the lungs, and one tubercle in a kidney. Cultures were isolated directly from the sputum. The cultural characteristics of the strain were practically identical with those of the strains from Cases 2 and 3. A rabbit inoculated subcutaneously with 24 mg. of the culture and killed 101 days later showed

a cystic caseous lesion, partial caseation of the nearest glands, scattered miliary tubercles in the lungs, and one tubercle in a kidney. A culture derived from the lung lesions of the rabbit was identical with the culture inoculated in cultural characteristics and in virulence for the rabbit. Two guinea-pigs inoculated subcutaneously each with 1 mg. of culture died of typical general tuberculosis in 75 days.

On the clinical side the cases have not presented any unusual feature. With regard to the biological properties of the strains isolated, it must first be noted how in most particulars the strains resemble the human type of tubercle bacillus. All the strains have produced in the rabbit and the guinea-pig the pathogenic effects of standard human tubercle bacilli. They resemble human tubercle bacilli also in their mode of growth on serum and glycerine serum. Microscopically the strains exhibited very irregular morphology, and there were many long, curved, and beaded forms both in the sputum and in cultures. They differ from standard human tubercle bacilli only in the way they grow upon glycerine agar, potato, and broth. On these media they are dysgonic, and save for very minor differences on glycerine agar have displayed characters which would entitle them to classification with bovine tubercle bacilli. The cultural features of three of the strains were practically identical. The other strain produced moderately good growth on agar, not equal to that of standard human tubercle bacilli, but growths definitely dysgonic on potato and broth.

The growths on serum and glycerine serum of all the strains so closely resembled those of standard human tubercle bacilli that at first I was of the opinion that my failure to get similar characteristic growths on other media was due to faulty technique —i.e., to the use in the tests of not sufficiently vigorous subcultures or to unfavourable media. The tests were therefore repeated again and again, but always with the same results. Two of the strains have been under observation for more than three years, and have been subcultivated on serum upwards of 60 times. Even after this prolonged subcultivation there has been manifested no increased capacity to grow on glycerine agar, potato, or broth. The same stability of cultural characters has been presented by each of the other strains after a period of observation of two and a half years. The distinctive cultural features of each strain have been retained also after subcultivation for several generations on glycerine serum and (of three strains) after passage through the bodies of animals (rabbits and guinea-pigs). These strains appear therefore to be stable new varieties of the tubercle bacillus, and on account of their closer resemblance to the human than to the bovine type of organism I have provisionally classified them as atypical human tubercle bacilli.*

The detection of these varieties of tubercle bacilli emphasises the importance of complete study of cultural characteristics of tubercle bacilli. In order to ensure that examples of this class of strain are not overlooked, it is essential to use for testing purposes not only a variety of glycerine media but also a serum which favours the production of pigment. The errors of classification which might have been made in these cases by a too restricted variety of culture tests are the following. If the serum used had been colourless or of poor quality distinctive (pigmented) growths would not have been secured, and the strains would have been classified as dysgonic with the pathogenicity of standard human tubercle bacilli. On the other hand, if the culture tests had been limited to egg and serum, with and without glycerine, the strains would not have been recognised as anomalous and would have been classified with standard human tubercle bacilli.

(c) *Analysis of Results obtained from Investigation of Sputum of 212 Phthisis Patients.*

The following table records the bacteriological results obtained in the examination of sputum from 212 cases of phthisis pulmonalis:—

	Number of cases.	Type of tubercle bacillus isolated.		
		Standard human.	Atypical human.	Standard bovine.
England... ...	139	135	2	2
Scotland... ...	73	70	2	1
Total... ...	212	205	4	3

It is notable that of my series of 212 sputum examinations 3 only (1·4 per cent.) yielded tubercle bacilli of bovine type. Also that in each of these 3 cases, though the sputum was repeatedly tested, none but bacilli of the bovine type were on any occasion isolated.† No other investigator in this country has cultivated from tuberculous sputum any but tubercle bacilli of human type, this result being recorded by Bulloch[3] and Cobbett[4] in regard to 23 and 2 cases respectively, and by Cruickshank[5] in reference to an unspecified number of observations. This great preponderance in pulmonary tuberculosis of the human to the exclusion almost of the bovine tubercle bacillus is in striking contrast to the relative frequency with which bovine tubercle bacilli occur in surgical tuberculosis and in the tuberculosis of childhood.

In this country, therefore, pulmonary tuberculosis which has arrived at the ulcerative stage is but very rarely referable to tubercle bacilli of bovine type. And elsewhere than in Britain an even smaller proportion of the sputa of persons suffering from pulmonary tuberculosis has yielded bacilli of bovine type. Out of 736 cases tested by foreign investigators 3 only yielded bovine tubercle bacilli; and further, in 2 of these 3 the bovine bacillus was only sparsely mixed with preponderating bacilli of human type, while in the third case proof was not afforded (only a single examination of the sputum having been made) that in this instance also both types of tubercle bacillus were not coexistent in the lungs of the patient.

(d) *Method of Obtaining Cultures of the Tubercle Bacillus by means of Antiformin.*

The simple method which I described in my last paper of obtaining cultures direct from sputum by means of antiformin has proved on more extended trial to be very trustworthy. This method was the outcome of the observation that the presence of free antiformin in a tuberculous fluid used for sowing cultures was not detrimental to the growth of the tubercle bacillus. There is no need, therefore, to centrifuge the bacilli and wash them free from antiformin before sowing. In fact, it is unadvisable in cultivation experiments to allow an antiformin sputum mixture to become so fluid that it is possible to centrifuge the bacilli. The method is carried out as follows:—

Equal volumes of dilute antiformin‡ and sputum are pipetted with a wide-bore pipette into a small test-tube and

* Since this paper was written Eastwood and F. Griffith have reported in the Journal of Hygiene (Vol. XV., No. 2, Jan. 14th, 1916) the isolation of similar atypical strains from cases of bone and joint tuberculosis. These strains will be more particularly referred to in my shortly forthcoming report on bone and joint tuberculosis, from which variety of tuberculosis I, too, have isolated several atypical strains.

† For details of these three cases see references 1 and 2.

‡ Antiformin, D.R.P., a mixture of sodium hydrate and Eau de Javelle.

thoroughly mixed. At intervals subsequently one loopful of the mixture is spread evenly over the surface of egg medium and the tubes are then incubated. By means of this simple procedure I obtained pure cultures of tubercle bacilli from 26 of the 31 new samples of sputum. In each experiment the volume of the sputum taken was about 1 c.c. and this was mixed with an equal volume of a 10 per cent. dilution of antiformin, thus forming a 5 per cent. antiformin sputum mixture. Egg tubes were sown with this mixture at intervals of 5 (sometimes 10) minutes during the first 30 minutes, the first tube being sown 5 minutes, occasionally 10 minutes, after the mixture was made. Tubes were also sown in many instances after longer intervals, up to 24 hours.

In 5 out of the 31 experiments the method failed. Twice all the culture tubes sown became overgrown in 24 hours, the antiformin not having been in sufficient amount to kill the microbes present in the particular sputum. In 3 experiments all the tubes sown remained sterile; tubercle bacilli were numerous in one of these sputum samples, scanty in the other two. In these three cases the concentration of antiformin was too high and tubercle bacilli as well as other organisms were destroyed.

In all the 26 positive experiments the mixtures were free from living organisms other than tubercle bacilli in 20 minutes or less. In 12 experiments pure cultures of tubercle bacilli were obtained after the antiformin had acted for about 10 minutes, and in 7 experiments after exposure for only 5 minutes. These experiments show how speedily organisms other than tubercle bacilli succumb to the action of antiformin. On the other hand, tubercle bacilli themselves did not long resist the action of 5 per cent. antiformin. In 13 experiments mixtures which yielded pure cultures of tubercle bacilli after 10 minutes' exposure to 5 per cent. antiformin were sterile after further periods of 5 or 10 minutes. The sputa in these cases were thin and mucinous, and in such sputa the resisting power of the tubercle bacillus is apparently little greater than that of the other microbes present. This was well shown in one experiment. An egg tube sown 5 minutes after the sputum and antiformin were mixed yielded an abundant growth of ordinary organisms after 24 hours' incubation. A tube sown 10 minutes after mixture grew a pure culture of tubercle bacilli. Tubes sown 15 and 20 minutes after mixture remained sterile. In several other experiments tubercle bacilli have appeared to survive other organisms not longer than 5 minutes.

It is evident from these results that with thin sputa the margin of time available during which pure cultures of tubercle bacilli are possible from a mixture may be very brief. When the sputum was thick the tubercle bacilli escaped early destruction, and such mixtures were found capable of producing cultures 24 hours after the sputum and antiformin were mixed. While 5 per cent. antiformin has given good results, so low a percentage has certain disadvantages for routine use. When the sputum is at all tenacious some time may elapse before organisms other than tubercle bacilli are destroyed and many may escape destruction altogether. Owing to this uncertainty it is necessary to sow cultures after many different intervals, thus greatly prolonging the period of the experiment. With a view of ascertaining whether higher percentages of the inhibiting agent would be more advantageous many comparative experiments with different proportions of antiformin have been made. In these experiments emulsions of tuberculous organs of guinea-pigs and rabbits have been employed as well as sputum.

The results of these additional observations, the details of which will be published at a later date, have led me to the conclusion that it is more advantageous, especially when dealing with tenacious sputum, to use high percentages of antiformin with short exposure than low percentages with long exposure. An opinion in this sense has also been expressed by McFadyean and Knowles.[6] For routine use 15 per cent. antiformin in the sputum mixtures is to be recommended, because there is not so much necessity for haste in sowing cultures as with still higher percentages. The first sowing should be made one to two minutes after mixture according to the consistency of the sputum, and three tubes at least ought to be sown within the first five minutes. Thereafter the intervals may be longer—five minutes—especially if the sputum remain undissolved and mucinous. There is no need to sow tubes after 20 minutes or after the sputum has completely dissolved.

The work here reported on has been carried out in the Pathological Department of the Field Laboratories, University of Cambridge, on behalf of the Medical Research Committee.

PAIN IN RENAL AND VESICAL LESIONS:

ITS CHARACTERISTICS, ITS ANOMALIES, AND ITS MISGUIDING MANIFESTATIONS, WITH 12 ILLUSTRATIVE CASES.

BY DAVID NEWMAN, M.D. GLASG.,
CONSULTING SURGEON, GLASGOW ROYAL INFIRMARY.

(*Continued from p. 674.*)

Causes of Pain in the Bladder.

LOCAL pain may be caused by any diseased condition of the bladder, giving rise to irritation of the terminal filaments of the sensory nerves supplying the mucous membrane, but as a rule little suffering is complained of unless the trigone or the neck of the bladder is involved in the lesion. When the pain is constant it is generally of a dull aching character and is located behind the symphysis pubes. Such pain is seen in encysted calculus at the base of the bladder and in chronic prostatitis. It is not relieved by emptying the bladder as it is in acute prostatitis, in tuberculosis, and in chronic cystitis. It is remarkable how free from pain some diseases are, such as papilloma, cystitis due to bacillus coli infection, and tuberculous disease involving the anterior wall. While, on the other hand, suffering, which may appear to be altogether out of proportion to the extent of the lesion, may be met with when it is located at the neck or in the first part of the urethra. Then the pain is sharp and agonising, especially during and after micturition. When the mucous membrane is intact the pain is not generally very great, but if it becomes eroded or ulcerated the suffering is more or less constant, is greatly increased when the bladder is evacuated, and the suffering continues after the termination of the act. With the exception of cases of stone the pain is worst at nights.

Referred pains in bladder affections extend more to the parts behind and below than to those above—that is to say, to the third and fourth sacral segments, and less frequently to the first, second, and third lumbar. So it is found that most patients complain of pain behind the sacrum, almost in the middle line, over the hips, and in the perineum, whereas a few may find that it extends to the back part and outer side of the hips or to the feet. (Fig. 6.) Occasionally pain passes to one or both kidneys, but how far this is due to nerve reflex or to backward fluid pressure it is often difficult to say. The conditions which cause pain are: (*a*) cystitis, especially when the lesion involves the neck of the bladder or the trigone, and when ulceration has been induced; (*b*) pericystitis; (*c*) retention of urine; (*d*) tuberculosis; (*e*) tumours; (*f*) rupture of the bladder; and (*g*) cystalgia.

Differential Diagnosis of the Renal Lesion Causing Pain.

Under normal circumstances moderate pressure upon the kidneys through the abdominal parietes does not produce pain or even discomfort; it may, indeed, be laid down as a principle that when such pressure induces pain there is some alteration in the kidneys. Undue tenderness shows itself in increased muscular resistance to pressure with the hands. In order to determine increased sensitiveness in the kidney, the patient lying upon his back with the knees well elevated by pillows, the surgeon should pass one hand behind the lumbar region, and with the other hand exert gentle but firm pressure in the direction of the kidney. When the muscular resistance is overcome and the pressure continued a peculiar, deep, dull, sickening feeling is experienced by the patient, which as a rule he can easily distinguish from the superficial aching consequent upon the compression of muscle.

Another method of determining the sensitiveness of the kidney is to give a sharp knock or tap in the lumbar region. In some diseases, most notably in renal calculus, a sharp, stinging pain is thereby produced. The one side should be carefully compared with the other. When present, increased sensitiveness is a useful guide, but its absence has no significance, as in many serious renal lesions pressure does not produce suffering.

Spontaneous pain in the lumbar region or in other well-recognised areas is the very common complaint in kidney disease, but its character and situation vary according to circumstances, and may often guide the surgeon in forming an opinion as to the nature of the lesion giving rise to the suffering. The feeling may only amount to a sense of uneasiness or discomfort; it may be a dull or gnawing pain; it may be very acute at times or may reach to a degree to be described as lacerating torture, accompanied by agonising spasms. The suffering may be of short duration, with intervals of complete freedom from pain, or it may be persistent. The less severe pains as a rule continue steadily in their course and are located in one place, while the more acute pains are generally remittent and extend over considerable areas. Dull persistent pain in most cases indicates a slow, steady change in the condition and bulk of the renal parenchyma or in the size of the pelvis, as is seen in tuberculous nephritis and in tumours. On the other hand, acute suffering is due to lesions which suddenly interfere with the exit of urine from the pelvis; for example, in calculus, in tuberculous pyelitis or ureteritis, or in obstruction from the impaction of a blood clot. Very often the patient is able to distinguish more than one kind of pain—a dull, gnawing, local pain which is persistent, and a sharp, spasmodic, remittent pain.

The diseases of the kidney in which pain is a prominent symptom embrace all lesions which involve acute inflammation of the renal parenchyma or the pelvis, and those in which there is a condition causing sudden interference with the circulation of blood or an impediment to the escape of urine.

We may now consider how far pain in the region of the kidney may assist us in forming a diagnosis. It is not possible to classify surgical affections of the kidney according to the presence or absence of pain, for the greatest variation in this respect may be observed in the same disease in different individuals, or, again, a lesion which at one stage gives rise to little or no suffering may at a later period cause considerable pain. It may be generally stated, however, that in diseases where the increase in bulk of the organ is slow, or the distension of the pelvis is very gradual, the lesion is not characterised by much suffering—for example, in simple chronic hydronephrosis, in polycystic kidney, and in tuberculous nephritis without pyelitis. In calculus impacted in the substance of the kidney little pain may be referred to the organ, whereas such diseases as pyonephrosis, suppurative nephritis, perinephritic abscess, tuberculous pyelitis, and calculus in the pelvis or in the ureter, usually give rise to considerable pain.

Paroxysmal pain coming on for longer or shorter periods, with intervals of complete relief, is generally caused by some obstructive lesion, calculous obstruction, torsion of the ureters, obstruction by pus, tuberculous débris, hydatid cysts, or blood clot, or from spasm of the ureters. It may also be caused by the poisons of rheumatism or of gout, or by some of the malarial poisons.

On the other hand, persistent pain of renal origin is most likely to result from some inflammatory affection of the pelvis and ureter, the presence of an impacted stone, the existence of rapidly advancing malignant disease or of a tuberculous lesion, with ulceration of the pelvis. Sometimes, also, persistent pain may be induced by the irritation of highly acid urine.

The conditions causing pain are: (*a*) Movable kidney—(1) traction on the pedicle, (2) passive hyperæmia, (3) transitory hydronephrosis, and (4) reflex disturbance; (*b*) congestion; (*c*) inflammation, acute and chronic; (*d*) hydronephrosis; (*e*) pyelitis and pyonephrosis; (*f*) cystic degeneration; (*g*) perinephric abscess; (*h*) tuberculosis; (*i*) renal calculus; (*j*) malignant tumours; (*k*) renal infarction; (*l*) nephralgia; (*m*) aneurysm of renal artery and (*n*) rupture of the kidney.

(*a*) *Movable kidney.*—In this disease pain is very variable in degree, so that for sake of discussion the cases may be divided into two classes: (1) Those in which ill-defined pain, generally abdominal, but not specially referable to the renal region, is the most marked symptom; and (2) those in which the pain is distinctly renal and is associated with (*a*) albuminuria only, (*b*) albuminuria and tube casts, (*c*) hæmaturia, (*d*) transitory hydronephrosis, and (*e*) pyonephrosis.

In the *first class* the pain is seldom or never severe. The point from which it seems to radiate is halfway between the lower end of the sternum and the umbilicus, but there is no tenderness on pressure at the epigastrium, so often observed in the pains of gastric disorders. In this group the pain does not in any way resemble renal colic, not being due to obstruction to the escape of urine, but rather to be attributed to traction on the nerves supplying the kidney or to pressure upon those lying close to it.

The pain is generally dull, and may amount rather to what the patient describes as an "unendurable sense of weakness" in the abdomen and a "tired feeling in the back." The pain often extends down the thighs, and is not infrequently mistaken for "sciatica" or "lumbago," or may be attributed to "rheumatism of the muscles" or "disease of the hip-joint." The pain, however, is not limited to the sciatic nerve, but extends occasionally in the course of the anterior crural. It is unattended with pain on pressure of the nerve trunks and is accompanied by frequent desire to micturate. The pain is not influenced by exposure

to damp or cold, nor is it increased by pressure over the painful part. There is no loss of motor power, nor is there atrophy of muscles. It is increased by exercise and relieved by rest, especially in bed. It is not prone to exacerbations during the night, nor is it increased by standing or pressure over the hip-joint. From time to time there may be digestive disturbance, especially if the patient has been taking much exercise of a rough kind. While the pain varies from day to day, there are intervals of rest and complete comfort. During the time that the pain is most severe there may be a feeling of nausea, the pulse is not affected, the temperature is unaltered, while after the attack passes away there may be a sense of utter prostration.

Medicinal treatment may relieve any digestive disorders when carried out along with rest in bed, and the pain may pass away, but as soon as the patient begins to move about again the old troubles all return. This occurs time after time. The patient loses courage, and thinking that no one "understands her complaint" she becomes resigned to her fate, and goes on suffering until the renal condition is revealed and an operation performed.

The *second class* forms one of the most interesting groups in that the pathology is clearly defined, and the most satisfactory results are attained by treatment. A circumstance I have observed, and one that is worthy of note, is that in these cases there are no signs of a neurotic tendency. In all, the symptoms are simply those due to mechanical obstruction to the circulation or to the escape of urine from the kidney. The first three symptoms—namely, albuminuria, the presence of tube casts, and the appearance of blood—are clearly due to the obstruction of the circulation; whereas the two latter, hydronephrosis and pyonephrosis, are due to the obstruction to the urinary flow. When we consider the changes that take place when the kidney becomes movable, the effects produced by twisting of the vessels, the nerves, and the ureter, it is easily understood how pain is produced. Impediment to the flow of the arterial blood to the kidney is very rare.

In all cases that belong to this group the pain is referred to the region of the kidney as the site of its origin or of its greatest intensity, but in severe cases the pain radiates far beyond the lumbar region. When the displacement is such as to obstruct the venous return only, the suffering comes on gradually and is of a steady, dull aching character. When it is so complete as to cause hæmaturia the renal pain may begin very suddenly, simulating renal calculus, and may be accompanied by severe gastric disturbance, nausea, and vomiting. Occlusion of the ureter causes more severe pain than obstruction to the venous return, is associated with more or less swelling from distension of the pelvis, and is accompanied by retention of urine. When the obstruction to the venous return is slight and of short duration, the only changes observed are a diminution in the quantity of the excretion and the presence of albumin; but if the obstruction be serious and prolonged, tube casts may be found in the deposit, and the organ is increased in size.

Torsion of the renal vessels and of the ureter may lead to one or more of the following symptoms: 1. Albuminuria with or without tube casts. 2. Hæmaturia, sometimes coincident with blood casts in the urine. 3. Dull, aching pain in the renal region almost constantly present, and associated with occasional paroxysms of colic similar to that produced by calculus. But while the paroxysmal pain, the hæmaturia, and the general gastric disturbance are similar in character and in mode of onset to what is observed in calculous disease of the kidney, in addition to, and frequently coincident with, the symptoms just mentioned, there is sudden diminution in the quantity of the urine. The subsidence of the renal pain is soon, but not immediately, followed by copious flow of urine of high specific gravity, instead of low as in transitory hydronephrosis. The hæmaturia associated with blood casts in the urine, and the renal pain concurrent with sudden appearance of albuminuria and tube casts, are important circumstances in forming a diagnosis.

Impediment to the escape of blood along the veins produces increased vascular tension, indicated by pain, in most cases by slight, but in a few by considerable, increase in the size of the kidney, and in many cases by reduction in the quantity of the excretion.

When frequently repeated over a long period venous obstruction is certain to lead to atrophy of the organ, but fortunately the sickness and pain induced by the condition force the patient to take rest in bed; thereby often the normal position of the kidney is restored and the twisting of the pedicle rectified.

Displacement of the kidney may lead to impediment to the flow through the ureter in various ways: (1) By kinking from rotation of the kidney on its short axis; (2) by obstruction from bending of the ureter in some part of its course; and (3) by occlusion of the lumen of the duct through angular insertion of the ureter into the bladder. I have seen only 19 cases where the hydronephrosis was sufficiently large to be detected by the hand as a distinct swelling in the lumbar region. But judging from the symptoms observed in many other cases, I have little doubt that occasional and slight obstruction of the ureter occurs frequently, lasting, however, only for a short time—too short a time to allow much fluid to accumulate. The duration of undoubted cases of transitory hydronephrosis varies considerably. In 12 of the 19 cases just alluded to, the duration was not less than six hours. In some the attacks extended over 48 hours, and in a very few lasted for days.

As I have already demonstrated in published cases[1] while the pelvis of one kidney is becoming distended the function of the opposite organ may be suddenly inhibited, as shown by complete suppression. Examples of reflex inhibition of the functions of the kidney are numerous. For example, unilateral obstruction due to the presence of a calculus in one ureter may cause complete anuria, which may last for a considerable time. In some the inhibition of the function of the healthy kidney occurs at once; in others it is only when the hydronephrosis on one side reaches a certain point that the kidney on the opposite side fails to act.

As a rule, transitory hydronephrosis of one kidney is not associated with immediate suppression of the function of the opposite organ. The suppression usually only follows after a considerable interval of hours or even of days. The suppression may be followed by albuminuria, and this may be limited to the urine which is excreted by the kidney opposite to the one which is hydronephrosed. Again, in cases of transitory hydronephrosis the

[1] Renal Cases, 1899, p. 39, published by James Maclehose and Sons, Glasgow.

excretion of the opposite kidney may not be stopped but only altered in character, the most marked changes being increase in the specific gravity and the presence of albumin.

Reflex functional disturbance is seen in some of the more severe cases. Not only are the gastro-intestinal symptoms pronounced and the functions of the kidney markedly interfered with, but in some there may be symptoms indicative of more remote reflex functional disturbance, as exemplified by derangement of the circulation or respiration, or of alterations in sensation. In one case I have observed complete anæsthesia of the mucous membrane of the bladder, and the patient was unable to micturate spontaneously for several weeks. These remote reflex symptoms are regarded and designated by some observers as "purely hysterical," a term the exact import of which has not, as far as I am aware, been defined. It is one commonly used to imply an attempt to counterfeit disease on the part of the patient. Does it not really, in most instances, serve as a convenient cloak for the ignorance of its creator when he is confronted with numerous and perplexing symptoms of the intimate pathology of which he has little knowledge?

These remote reflex symptoms of movable kidney may be seen in patients who have very perfect mental control, and in whose case the suggestion of either partial or complete suspension of inhibitory mental influence at any time could not be entertained. But while this is true in some cases, in many others the patients are distinctly devoid of self-control and given to exaggerate their suffering, and sometimes even to mimic diseased conditions. It is therefore extremely difficult for the surgeon, unless he makes a very careful study of the individual case, to say how far the reflex phenomena are actual or assumed, but to conclude that in all instances they are the result of morbid mental conditions is very apt to lead one into serious error.

CASE 7. *Movable right kidney, with onset of symptoms characterised by marked respiratory and digestive disturbance; local symptoms at first trivial.*—The patient I saw at Uppingham, with her family physician, and he told me that when he was asked to see her in October, 1902, the first symptoms were those of acute gastro-intestinal disturbance. On making an abdominal examination he found the right kidney freely movable, but the patient did not complain of pain in the renal region, and the urine was found to be strictly normal. Mr. H. Lyon Smith regarded the case as one in which the gastro-intestinal disturbance was due to the displacement of the right kidney. He ordered rest and the application of an abdominal bandage and kidney air-pad, with the result that she enjoyed good health till May, 1904. He noticed that the symptoms were present only while, or immediately after, the kidney was displaced; and he maintained, and in this I agree with him, that there was no "hysterical" element in the case.

The patient was an extremely quiet, sensible woman. Mr. Lyon Smith wrote to me, saying:—"In May of this year I was called hurriedly to see her, on account of a 'suffocative attack.' I found her walking about the room very flushed and anxious-looking, breathing very quickly, about 80 shallow inspirations per minute; pulse very small and thready, 110 per minute. The attack resembled one of angina, except that the face was flushed rather than pale."

The heart and lungs were free from any organic disease. During June and July, while the patient was permitted to move about, and the kidneys occasionally became displaced, these attacks were frequent; but with complete rest they soon disappeared, and with medicinal treatment her general health improved. The conclusion Mr. Lyon Smith came to was that "the suffocative attacks were caused by the movements of the right kidney setting up a sudden disturbance of the sympathetic nervous system," and when the kidney was kept at rest the attacks ceased.

The patient came to Glasgow and I had her under observation for over three weeks, and from what I saw I am convinced that Mr. Lyon Smith's explanation is correct. We are very familiar with gastro-intestinal symptoms as a result of movable kidney, but marked respiratory disturbance is uncommon. I have seen a few instances similar to, but much less marked than, the one just described, but in most of them the patients were easily excited, and in many, if not in all, I was unwilling to admit the possibility of reflex irritation. In this case I think we have clear examples of reflex functional disturbance directly resulting from the displacement of the kidney.

(*b*) *Passive congestion* as seen in chronic cardiac and pulmonary diseases or from pressure on the main veins does not cause pain, but there is a dull, aching feeling in both the lumbar regions, which is usually worst at night, is not eased by fixation, and is aggravated by firm deep pressure. On the other hand, in lumbago the pain is more severe in the morning, becomes easier as the day advances, is relieved by fixation, and is as a rule more marked on one side. In passive congestion the urine is diminished in quantity and contains albumin, and sometimes blood-casts. The effects of passive hyperæmia have already been described under movable kidney.

(*c*) *Inflammation, acute and chronic.*—In septic nephritis and other acute infective diseases pain may be a marked symptom, and the amount of suffering depends upon the degree of tension of the capsule. In acute nephritis the pain is dull and aching and there is tenderness on pressure both in front and behind and even to percussion. It is never paroxysmal and never referred. The pain is not limited to one side, but extends across the back, as generally both kidneys are involved. When it ceases to be limited to the lumbar region a general toxæmia is indicated and an unfavourable result may be expected.

The points to attend to in the diagnosis are: 1. The situation and character of the pain. 2. Presence of blood corpuscles, albumin, and tube casts in the urine. 3. General constitutional disturbance, loss of appetite, nausea, and vomiting, fever, high pulse and dry skin, œdema. 4. Scanty, cloudy urine.

(*d*) In *hydronephrosis*, as a rule, severe pain is only induced when the obstruction of the ureter is sudden and complete or nearly so, or as a consequence of pressure of the distended kidney on the neighbouring structures. In the majority of cases of chronic hydronephrosis recorded the patient suffers more from a sense of weight and dragging than actual pain. Intermittent hydronephrosis as seen in movable kidney has already been referred to, but it is also a result of temporary obstruction in the pelvis or the ureter from lodgment of calculus, blood clot or fragments of tumour. In these cases the pain assumes the characters of renal colic, and it is often very severe and widely distributed. Hydronephrosis is frequently associated with other painful affections, such as cancer of the uterus or bladder, prolapse of pelvic organs, or impacted calculus, and an amount of suffering may be attributed to the distension of the renal pelvis for which it should not be blamed.

The amount of pain does not, however, depend upon the size of the hydronephrosis, but rather upon the circumstance whether the obstruction leading to it is acute or chronic in its nature.

Sudden pain coming on in a case of chronic hydronephrosis, in which the patient has been free from suffering for a considerable time, and especially if the onset of the pain is preceded by a strain, blow, or other injury, should suggest rupture of the hydronephrotic sac into the peritoneal cavity. In such circumstances the pain assumes the characters of that of peritonitis—sudden sharp pains with marked rigidity of the abdominal walls, with general tenderness; rapid pulse becoming thready; temperature subnormal or febrile.

The points to attend to in diagnosis are: 1. Distinct swelling in the lumbar region coincident with diminution or suppression of urine, and the sudden relief of pain being associated with the passage of a large quantity of urine of low specific gravity. This may be followed by some hæmaturia. 2. Chronic dragging pain in the back with occasional exacerbations. 3. Injections of collargol into the renal pelvis demonstrate the extent of the distension when viewed with the X rays.

(*e*) In *pyelitis and pyonephrosis* pain, except of a dull, dragging kind, may remain absent for a considerable time. Severe pain may be experienced without any distension of the pelvis. The pain is of much the same character as in hydronephrosis, except that it is more marked in the kidney zones, and the tenderness on pressure over the kidney in front is more pronounced and more constant. It is associated with frequent and painful micturition, pain in the penis, and extending down the back of the thighs.

In suppurative disease of the urinary tract the effect produced by toxins may give rise to painful affections simulating lumbago, rheumatism, gallstone, renal or vesical calculus, and appendicitis, which symptoms diminish or disappear on the employment of a vaccine prepared from the organisms isolated from the urine, even although the quantity of pus and the number of organisms in the urine may not be diminished; the antitoxins evidently neutralising the effect of the toxin so that their harmful effects cease to be evident.

In suppurative diseases of the renal pelvis the absence of pain depends upon the circumstance of free escape of the excretion into the bladder. Should this be intercepted temporarily the increased intrarenal tension may cause severe paroxysms of renal colic. Pressure over the kidney may provoke much pain, and palpation by abdominal, rectal, or vaginal examination may reveal thickening of the walls of the ureter. If there is a large collection of pus in the pelvis of the kidney, and especially should the suppuration be induced by the presence of a calculus, rupture may take place into the abdomen or into the space behind the peritoneum.

The points to attend to in the diagnosis are: 1. Swelling in the lumbar region gradually increasing in size, during which time there may be little pus in the urine. 2. Pain steadily increasing, with febrile symptoms, relief of pain coincident with discharge of pus, which may be seen by the cystoscope escaping from the ureter of one kidney. If the case is a very chronic one the pus may form small casts of the ureter which lie in the bladder like a collection of maggots. These casts, of course, are destroyed when the urine is passed per urethram. Pain is usually limited to the lumbar region, and is increased on pressure, but not by movement.

(*f*) In *cystic degeneration* pain is undoubtedly rare, unless suppuration or some other complication has set in. In simple cases of polycystic kidney the patient may complain of dull aching in the renal regior, sometimes of a sickening character. Usually there is only a sense of general discomfort as a consequence of the size and weight of the kidney, but there may be exacerbations resembling renal colic if the cystic kidney has become movable. These attacks are due to transitory hydronephrosis rather than the cystic degeneration. In many cases there is much tenderness on pressure. Spontaneous pain is distinctly local and is seldom severe, unless when pressure is exercised by the weight of the kidney pressing on the lumbar plexus, or by a pyonephrosis being established.

The points to attend to in diagnosis are: 1. A non-fluctuant swelling in one or both loins—rounded, nodulated on the surface; the renal form of the organ is retained; it is not painful on pressure, nor does it increase or diminish from time to time. 2. Hæmaturia may occur, but is not frequent or severe. 3. The urine is large in amount, low specific gravity, and contains some albumin, but no pus. 4. Cardiac and arterial charge may also indicate the character of the disease.

(*g*) In *perinephritis and perinephritic abscess* the pain is severe and lacerating from the beginning and increases steadily. On account of the location of the lesion the lumbar plexus becomes involved, and consequently the pain is referred to the distribution of the nerves supplied therefrom. This explains why in chronic perinephritis the pain in the thigh or knee may be mistaken for that of hip-joint disease. Areas supplied by the anterior crural, the external cutaneous, and the genito-crural are also affected. There is great tenderness on pressure, motion is controlled, and the patient is unable to bend forward or back, associated with local elevation of temperature and rigors, preceding the appearance of swelling and fluctuation in the lumbar region.

It is usually first located in the loin, but may extend along the distribution of the nerves of the lumbar plexus later, and as a rule it continues until the pus is evacuated. In chronic cases the surgeon is apt to be deceived by the absence of pain, and the patient may be deluded into the hope that a good recovery has taken place. The constitutional disturbance, however, remains, and it is only when the pus is freely evacuated that a relief from pain can be looked for.

The points to be attended to in diagnosis are: 1. A diffuse, posterior swelling not limited to the renal region, fluctuant, and associated with fixation of the lumbar spines and curvature towards the diseased side. 2. Pain in the lumbar region increased on pressure from behind, with reflex pain in the areas of the lumbar plexus. 3. Gastro-intestinal symptoms, sickness, vomiting and tympanites, febrile temperature, white blood corpuscle count increased. 4. No hæmaturia or pyuria.

(*h*) *Tuberculosis* of the kidney is not characterised by severe pain, but commonly the patient complains of a dull, dragging sensation in the loins. Pain in renal tuberculosis depends upon whether or not the pelvis and ureters are involved in the disease. When limited to the cortex the area of tenderness is most marked in the lumbar region close to the tip of the fourth lumbar transverse process. Pain is seldom severe when the parenchyma only is implicated, and rarely amounts to more than a dull, dragging sensation in the loin. Agonising suffering is sometimes endured, however, in cases of tuberculous pyelitis and when the disease involves the ureter and bladder. This is specially seen when the flow of urine is impeded by the ureter becoming obstructed by blood clot, tuberculous débris, or by induration of the walls of the duct. In such instances the pain is associated with

frequent micturition, and comes on in paroxysms like those of nephritic colic, and is often temporarily relieved by a copious flow of urine. Strangury is present in almost all varieties of the disease, but there is seldom an escape of blood with the last drops of urine unless the bladder is involved, and the pain and frequency are almost as marked when the patient is at rest in bed as while moving about. The greatest discomfort is referred to the bladder, which, when it becomes distended, causes considerable suffering before and during micturition, but the pain is relieved immediately the bladder is empty.

The points to attend to in diagnosis are: 1. Enlargement of the kidney with tenderness most marked in the lumbar region at the point of the fourth lumbar transverse process. 2. Slight hæmaturia, polyuria and pyuria, with tubercle bacilli in the urine. 3. Frequent and painful micturition with evidence of irritation of the orifice of the ureter on the diseased side and purulent urine escaping from it. 4. Tuberculin reactions positive. 5. Febrile temperature and probably evidence of tuberculosis elsewhere.

(i) The pain associated with *renal calculus* varies according to the situation and composition of the stone, and according as there is, or is not, pyelitis. It may be stated generally that when the calculus is impacted in the substance of the kidney, and uncomplicated by pyelitis, there is comparatively little suffering, or severe pain may exist for a time and then disappear for years. In other cases there is a dull pain almost constantly present in the loin. If the calculus is in the renal pelvis, or moving freely in a cavity within the kidney, pain becomes a more marked symptom, and is not limited to the loin, but extends to the testicle, to the penis, and the inner aspect of the thigh. When the stone is impacted in the ureter the action of the psoas muscle in walking may aggravate the pain.

When the calculus is so situated the pain is dependent upon movement, being aggravated by exercise of any kind, or even by movements in bed, while complete rest generally affords marked relief. The varying pressure of the abdominal viscera, or changes in posture, may modify the pain, or palpation either in the back or of the abdomen may cause it to be temporarily increased.

Immediately a stone enters the ureter renal colic sets in, and the paroxysms, coming on often without warning, may last for hours or days. The pain is agonising, and radiates from the region of the kidney down the ureters to the thigh, penis, and testicle. When the first sickness and faintness, so characteristic of renal colic, have passed off, the patient may endeavour to relieve himself by contortions in all directions, or may be thrown into convulsions by the fearful agony he is suffering. After a period of great anguish, usually measured by hours, the pain subsides as suddenly as it came on, and the other symptoms accompanying it disappear. If the calculus passes into the urinary bladder the patient may be sensible of the fact, but if the stone has merely become displaced from the renal orifice of the ureter another paroxysm may occur at any time. In other cases the calculus remains impacted in the ureter, which becomes more or less habituated to its presence. Under such circumstances, although the pain may set in suddenly, it becomes only gradually relieved, and cessation of suffering alternates with paroxysmal attacks, probably caused by spasm of the ureters.

In renal calculus the pain is not entirely due to the direct irritation of the stone or to the obstruction produced by its impaction. Another factor must be admitted. The presence of the calculus in most instances induces a congested condition of the renal parenchyma, and this increased vascular tension is of itself the cause of much suffering. The fact is well illustrated by the relief experienced by patients after a free hæmaturia or by a cupping in the lumbar region.

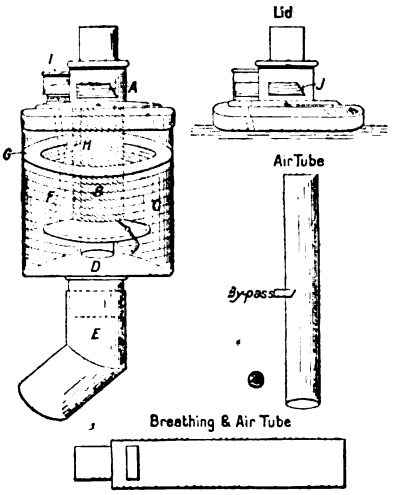
CASE 8. *History of renal calculus for 20 years; repeated attacks of renal colic, and passage of stones and gravel from both kidneys; frequent hæmaturia and occasional pyuria; pain often relieved and general condition improved by a profuse hæmaturia; nephrolithotomy.*—The patient was admitted to the "Central Home" on account of an acute attack of calculous pyonephrosis in the left kidney. He gave me a long and interesting history of his illness, which commenced over 20 years ago. During that long period he had many attacks of renal colic, and not infrequently they were associated with the appearance of pus or blood in the urine. He took a very intelligent interest in his illness, had studied his own case carefully, and observed that when the pain came on, preceded by the usual premonitory symptoms of an attack, which he readily recognised, if he took a long ride on horseback until he was exhausted, a profuse hæmaturia was induced, unaccompanied by the passage of stone or gravel. This gave him much relief from the pain, and for several weeks thereafter his general health improved. A stone weighing half an ounce, and of the form and size of an index finger, was removed, and the patient made a good recovery.

It must be borne in mind that renal colic may arise from any sudden stoppage of the ureter, by disease of its walls, by a foreign body, by pressure from without, or by torsion. Hence, we find that although renal calculus is the most frequent cause of severe paroxysmal pain, this symptom may likewise occur in tuberculous disease from the passage of a caseous mass or a plug of mucus, or as a consequence of a tuberculous ulcer. In hydatid disease severe suffering may arise from the evacuation of cysts, or in tumours of the kidney from portions of the growth becoming detached and carried down the ureter.

As shown by Prout—and Dickinson agrees in his opinion—the pain is not equally severe in all varieties of renal calculus. The latter says "that of renal concretions lithic acid produces the least pain, what there is being dull, oppressive, and connected with a sense of weight; oxalate of lime causes pain of a more acute kind, and that often referred to a particular spot over the region of the kidney, and sometimes discursive, shooting in the direction of the ureter, epigastrium, or shoulder." Calculi composed of phosphates are "found to be attended by great suffering—almost unremitting, though paroxysmally aggravated."

Pain such as described must be regarded as one of the most important indications of renal calculus, and may of itself, if sufficiently characteristic and aggravated, justify the surgeon in making an exploratory incision even in the absence of other symptoms.

The points to attend to in diagnosis are: 1. The diagnosis of renal calculus has been made easy and certain by radiography. It is the short cut to diagnosis, but should not be allowed to supersede all other methods, only used along with them. 2. Pain is generally associated with hæmaturia and often with pyuria. 3. Pain is increased by manipulation and by exercise, and is relieved by rest. 4. The ureter orifice on the affected side is abnormal and the urinary shoots increased in number. 5. Reflex symptoms are common during attack of colic, and urine may be suppressed from one or both kidneys.



(To be concluded.)

A SIMPLE PERCENTAGE CHLOROFORM INHALER.

BY CHARLES T. W. HIRSCH, M.R.C.S. ENG., L.R.C.P. LOND.,

TEMPORARY CAPTAIN, R.A.M.C.; ANÆSTHETIST, ROYAL HERBERT HOSPITAL, WOOLWICH, ETC.

THE principle of this inhaler was originally brought out in Paris, and introduced in a modified form to English clinical medicine by Professor A. D. Waller. As a result of working with an inhaler lent to me by Professor Waller, this apparatus has been devised chiefly because it permits greater ease of application to the patient's face, irrespective of the patient's position, and a freer air-way. As the illustration shows, the apparatus consists of a metal cylinder divided by a thin domed false bottom into two chambers. The lower one is coned to take an ordinary gas face-piece, and is provided with a movable angle connexion for use when the patient is on his side or face. A central tube passes through the lid and upper chamber terminating in the false bottom, and conveys air directly to the face-piece. It is surrounded by an air cone which is expanded below over the false bottom in a baffle-plate. A by-pass passes from the upper chamber through the cone and projects into the air tube. The air cone is provided with an opening or port, admitting air to the upper or chloroform chamber. The size of the port is regulated by a movable

The percentage chloroform inhaler and its component parts:

A, Port or air inlet closed.
B, Absorbent wick for chloroform around central cone.
C, Absorbent wick around walls of chamber.
D, Hollow dome.
E, Detachable tubing for fixing to respirator.
F, Chloroform tube.
G, Baffle-plate.
H, Chloroform by-pass to air chamber.
I, Inlet for chloroform.
J, Port opening left to right.

collar on the lid, and an indicator shows the percentage of chloroform which is passing to the face-piece. The upper chamber is surrounded inside with wick, and also has wick round the inner cone. Both wicks touch the bottom of the upper chamber, the latter one by passing through a hole in the baffle-plate. The lid is removable, but to save taking it off during the administration of the anæsthetic a screw-on cap in the lid permits the addition of chloroform to the upper chamber. The wicks can be removed, and the whole apparatus can then be sterilised.

To use the inhaler 6 drachms of chloroform are placed in the upper chamber, which saturates both wicks and leaves a layer on the false bottom, below the baffle-plate but not touching the latter. The port is closed. An ordinary gas face-piece is attached to the coned end, either directly if the patient is on his back, or if in another position by means of the detachable angle-piece. The face-piece is then adjusted to the patient's face, so that the only admission of air is by the air-tube. Pure air is then breathed. As the port is opened chloroform vapour is drawn through the by-pass in the same way as air is sucked in a Bunsen burner or Fletcher gas stove. The expirations of the patient maintain a constant temperature in the chloroform chamber, and from actual experiments at that temperature the dial on the lid is graduated to show the percentage being inhaled. In use it is found advisable to start with the port closed, indicator at zero, and to take 10 minutes in passing gradually to 2·5 per cent. when surgical anæsthesia is generally produced. A higher percentage is rarely needed. Anæsthesia when obtained can be maintained at from 1 to 2 per cent. The only important point is to make a gas-tight joint between the face and inhaler, which can always be obtained by the use of an appropriate sized face-piece.

I have used this apparatus in more than 1000 cases, some of over two hours' duration, and have found it most efficacious. The advantages claimed are the ease of adaptation to the patient's face, irrespective of his position, the perfect air-way, and the certainty of the percentage of chloroform, as well as the simplicity of the inhaler, which is without valves or parts that can get out of order. Experiments made by drawing air by aspiration from the chloroform chamber have not revealed any increase of carbon dioxide, thus showing the absence of rebreathing.

The apparatus can be obtained from Mr. Cliff, motor engineer, of Well Hall, Kent.

I wish, in conclusion, to express my indebtedness to Professor Waller, who has kindly verified the chloroform percentages on his chloroform balance.

Kensington Palace Mansions, W.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

A CASE OF ECLAMPSIA WITH TRIPLETS. TWO OF THE CHILDREN BEING UNITED.

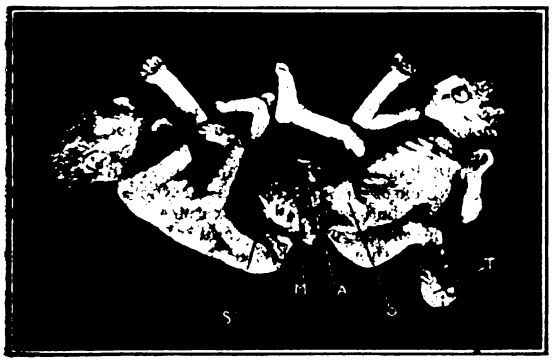
BY ROBERT JARDINE, M.D. EDIN., &C.,

PROFESSOR OF MIDWIFERY, ST. MUNGO'S COLLEGE; PHYSICIAN AND GYNÆCOLOGIST, GLASGOW ROYAL MATERNITY AND WOMEN'S HOSPITAL.

THE following case of eclampsia is an interesting one, as it was one of triplets with two of the children united. With triplets the risk of eclampsia is very much greater than with single pregnancies, as the strain upon the mother's system is enormously increased.

Mrs. ——, primigravida, aged 23, was admitted to the Glasgow Royal Maternity and Women's Hospital on Dec. 5th, 1915, suffering from eclampsia; there had been five severe fits. On admission she was very obstreperous and was with difficulty kept in bed. She complained of violent headache and failing sight, but was not quite blind. There was great œdema of the face, body, and legs. The abdomen was very much distended, and on palpation it was impossible to make out any fœtal parts, neither could the fœtal heart be heard. The case was looked upon as one of multiple pregnancy. The urine was heavily loaded with albumin. The os uteri admitted two fingers and the cervix was taken up. Labour had commenced. There was a head well engaged in the pelvis. She was supposed to be eight months pregnant.

The patient was given a saline transfusion of 2 pints (5 i. each of sod. chlor. and sod. acet. to the pint) under the breasts, a large dose of Epsom salts by the mouth, and 0·5 c.c. trivalin hypodermically. A fit occurred after the transfusion, but there were no more. She soon became quiet and the labour passed off. On the 6th the sight was



normal and the headache had ceased. The bowels had been well cleared out and the kidneys were acting well. There were no labour pains.

On the 7th labour came on again, and at 6 P.M. the membranes ruptured spontaneously. As the head did not advance it was decided at 8 P.M. to deliver with forceps. The instruments were applied by Dr. Grace Whish and the head was easily delivered, but when the body came down there was difficulty with the breech. Another breech was discovered to be coming and the two were attached. The two children were got away by making strong traction upon the first one; the perineum was torn. Another child was found to be in the uterus in an unruptured sac. The membranes were ruptured and a live male child was delivered with forceps.

The uterus remained very flabby and a severe post-partum hæmorrhage came on. The two placentæ were removed, and as the uterus did not retract under the stimulus of kneading and a hot douche, it was quickly packed tightly with iodoform gauze. Hypodermic injections of ergotin and pituitrin were given and a saline transfusion of two pints. The pulse, which was very feeble, soon began to improve and by next morning was fairly good, about 108. She had passed a large amount of urine and the albumin had lessened. When the packing was removed the uterus was very firmly retracted, and there was no bleeding. Considering what the patient had come through she was very well, and the prognosis looked hopeful, but next morning she began to complain of severe pain at the base of her right lung, and her breathing became very embarrassed. It was evident that pneumonia was setting in. Hot antiphlogistine applications somewhat relieved the pain, but the breathing became more embarrassed and the pulse began to fail. Death occurred at noon, 40 hours after delivery.

The united children (females) were alive and apparently strong. They weighed 6 pounds. As they lay covered in a cot buttock to buttock they looked like two normal small children. Urine was passed, but no meconium. Small quantities of milk were taken quite readily. They did not seem to suffer much, but gradually lost flesh, dying on the 13th at 6.10 A.M. The single child, a male weighing 6 pounds, was a fine sturdy little fellow, and was thriving well a few days later when taken home.

The placentæ weighed 1½ lb. each. The cord of the single child was 20 inches long. The united cord, which was only about 3 inches long, had been torn off at the placenta. The shortness of the cord had prevented the descent of the head.

Photograph of the twins showing the two connecting stalks (S), the central mass (M), the severed edge of the fused amnions (A), and the talipes (T). The insertion of the umbilical cord was on the opposite side of the mass from M.

I am indebted to Dr. J. F. Gemmill, lecturer in embryology, Glasgow University, for the photograph here reproduced, and for the following note:—

"Dr. Jardine's specimen is of very great interest for the reason that it appears to be the only well-authenticated instance among mammals of twins with ventral union limited, as far as the parietes are concerned, to the umbilical region. With a single doubtful exception dating back to the fourteenth century, all other recorded examples of ventral or "Siamese twin" union exhibit fusion to a greater or less extent, either in the thoracic (thoracopagus) or in the pelvic (ischiopagus) regions. The sub-type omphalopagus must accordingly be recognised in the future classifications of mammalian double monstrosities, its position being intermediate between the two sub-types just named. A detailed account of the specimen is being prepared by one of my students, Mr. James Stewart, and myself."

Glasgow.

A CASE OF FULL-TERM EXTRA-UTERINE PREGNANCY; OPERATION.

BY J. F. DEVANE, M.D. N.U.I., F.R.C.S. IREL.,
HONORARY SURGEON, LIMERICK COUNTY INFIRMARY, AND ST. JOHN'S HOSPITAL, LIMERICK.

FULL-TERM extra-uterine pregnancy is a rare condition, and the following notes on a case may be of interest.

The patient, aged 38, was married seven years ago. Three months later she had a miscarriage, was curetted, and a year afterwards a child was born. In February, 1913, she had a second miscarriage. Menstruation was then regular until May, 1914, when it ceased, but returned again in July; from then until December she was unwell every two or three weeks, and suffered from slight abdominal pains and general discomfort. In December menstruation stopped and did not return for five months—i.e., until April, 1915, a week before admission to hospital. At that time she had a "flooding" and bearing-down pains. A midwife attended her and told her she had had a miscarriage—that "the little birth had come away," but that she had a large tumour for which she would require hospital treatment. On examination the uterus was found enlarged, reaching two inches above the umbilicus; the os was patulous and admitted the index finger; there was a blood-stained discharge from the vagina. Behind the uterus a large cystic tumour was felt filling up the pelvis and occupying most of the abdomen. Lactate of calcium was administered for a few days. The abdomen was opened by a long median incision. The uterus was first sought for and found above the pubes, in contact with the anterior abdominal wall. Behind the uterus a large cystic tumour was found filling up the pelvis below and reaching almost the diaphragm above. Coils of small intestine were adherent to its anterior and upper surfaces. The adhesions were sponged off, or ligatured and divided, and the tumour was brought partly into the wound and packed round with sponges. A large trocar was introduced and several pints of dark-coloured fluid were withdrawn. The sac was then slit up freely and a well-developed full-term male child was found lying in the left occipito-anterior position. The cord was divided and a stillborn child extracted. A large placenta was found adherent to the floor of the pelvis and stretching up along the back of the uterus. This was sawn off with the finger-tips. Considerable hæmorrhage occurred from some of the vessels near the centre of the placental site, where thrombosis had not completely taken place. This was dealt with by forceps, and hot sponge pressure, and a saline infusion was given into each axilla. The superfluous portion of the sac was removed, and remaining pelvic part was plicated by means of a couple of rows of purse-string suture passed around its inner surface; thus the large pelvic space was converted into a cylindrical tube. This was sutured to the lower angle of the abdominal wound and a drainage-tube passed into it. The drain was removed on the third day; a slight seropurulent discharge persisted for a fortnight from the gestation sac. The remainder of the abdominal wound healed by first intention.

The condition might easily have been mistaken for a five months' miscarriage, associated with a large ovarian or intraligamentous cyst. The duration of the amenorrhœa corresponding with the size of the uterus, the signs of recent delivery, and the nurse's statement pointed to a miscarriage; the gestation tumour resembled a large cyst—there were no fœtal movements, no fœtal heart, the excessive amount of liquor amnii and the adherent intestine rendered difficult the palpation of the fœtal parts, whilst the large placenta spread out behind the uterus masked the fœtal head.

A report of the patient on Feb. 14th, 1916, states: "Menstruation returned three months after the operation and lasted eight days. She has been unwell about every three weeks since then, and at the present time she is feeling quite strong and healthy."

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF OPHTHALMOLOGY.

Discussion on Disturbances of Vision from Cerebral Lesions, with Special Reference to the Cortical Representation of the Macula.

A MEETING of this section was held on March 22nd, Sir ANDERSON CRITCHETT, Bart., C.V.O., being in the chair.

Colonel W. T. LISTER, C.M.G., A.M.S., and Lieutenant-Colonel GORDON HOLMES, R.A.M.C., read an introductory paper upon the subject to be discussed. They stated that in their work at the base hospitals in France during the past 18 months they had observed a very large number of cases in which the vision was affected by lesions of various portions of the optic system. By selecting for thorough examination a certain number of suitable cases, a group of facts had been collected which had an important bearing on the cerebral localisation of vision, more particularly on the representation in the cortex of different regions of the retina. It might be objected, they said, that as the observations were necessarily made at an early stage after the infliction of the injury some of the effects observed might have been due to functional disturbances rather than to local injuries of the corresponding cortical areas or their centripetal fibres. But if it could be shown that there was a constant relation between the probable site of the injury and the form of the visual defect, certain general conclusions would be at least justifiable. The injuries in the cases referred to included penetrating wounds of the cranium by rifle bullets, shell fragments, and shrapnel, as well as local concussion and depressed fractures. The probable positions of the cerebral injuries were determined by careful measurement of the entrance and exit wounds from fixed points, such as the external occipital protuberance, the relation of which to the calcarine fissure and optic radiations being known, by means of radiographic examination, and by observations made at the time of operation, &c. The notes of 21 cases were recorded. The first group contained instances of quadrantic hemianopia, and from these it was concluded that the upper half of each retina is represented in the upper part of the visual area, and *vice versa*. In the second group several cases of absolute or partial central scotoma were described; in all these the lesion was probably limited more or less completely to the posterior extremities of both occipital lobes. Consequently it appeared probable that the centre for direct macular vision lay in the posterior part of the visual area. This conclusion was supported by the fact that among over 2000 cases of head injuries they never saw a central scotoma where a direct injury of the occipital poles could be excluded. Further, they described cases of homonymous hemianopia with loss of central vision in the opposite halves of the visual field in cases where the optic radiations or the visual centres had been destroyed on the one side, while the lesion was limited to the occipital pole of the other hemisphere. The above conclusion was also supported by another large group of cases—viz., those with paracentral scotomata. In each of these cases the lesion involved only the posterior part of the visual area, and it was found that when the upper portion of the posterior part of the calcarine cortex was injured, the paracentral scotoma involved central vision immediately below the fixation point in the opposite halves of the visual field, and *vice versa*. It was consequently probable that the upper part of the macula lutea and the surrounding retina were also represented in the upper part of the visual area, and *vice versa*. They believed that the hypothesis of bilateral representation of the macula was unnecessary and incorrect on the following grounds—viz., that the above-mentioned paracentral scotomata usually extended right up to the fixation point, and also that in the hemianopia produced by penetrating wounds which involved one occipital lobe, there was not usually the "macular escape," such as was so frequently seen in the hemianopia due to vascular lesions. They suggested that this "macular escape" was probably due to the fact that the tip of the occipital lobe, in which central vision was represented, was a watershed area, which might draw its blood supply from either the middle or the posterior cerebral arteries; the variation in the respective distribution of these arteries, they believed, might account for the escape or the involvement of vision in the neighbourhood of the fixation point. The interesting question was raised as to whether vision for colours might be dissociated from that for white—in other words, whether an achromatopsia could be produced by cerebral lesions. They considered, however, that they had gleaned no conclusive evidence that achromatopsia, with intact vision for white, was produced by cerebral lesions which involved either the cortex or the optic radiations. The authors' conclusions, which they did not yet regard as final, were formulated as follows: 1. The upper half of each retina is represented in the dorsal, and the lower in the ventral part of each visual area. 2. The centre for macular or central vision lies in the posterior extremities of the visual areas, probably on the margins and lateral surfaces of the occipital lobes. 3. That portion of each upper quadrant of the retina in the immediate neighbourhood of, and including the adjacent part of the fovea centralis, is represented in the upper and posterior part of the visual area in the opposite hemisphere, and *vice versa*. 4. The centre of vision for the periphery of the retinæ is probably situated in the anterior end of the visual areas, and the serial concentric zones of the retina from the macula to the periphery are probably represented in this order from behind forwards in the visual area. The paper concluded with a grateful acknowledgment of the assistance received by the authors from the medical officers of the various hospitals in which the cases were observed, and their thanks to Captain Curtis Webb for help in the preparation of the illustrations.

Sir ANDERSON CRITCHETT, in expressing the gratitude of the section to the authors for their painstaking research, referred to the rapid strides made by brain surgery, and the unexampled opportunities afforded by the present conflict to make advances in surgical and medical knowledge.

Lieutenant-Colonel R. H. ELLIOTT asked whether Colonel Lister and Colonel Holmes were able to confirm the estimate as to the efficacy of the steel helmet in preventing head injuries. He also referred to the greater severity of wounds inflicted by bullets which struck in the first 250 yards of their flight, before they had settled down to a steady onward course, as compared with those which found their billet at distances between 250 and 1000 yards.

Captain A. W. ORMOND suggested a possible confirmation of the authors' thesis in the central scotoma met with in some people who were subject to megrinous attacks. It was probably a vascular phenomenon, dependent upon the macular centre being placed at the posterior pole of the occipital lobe.

Mr. LESLIE PATON urged ophthalmologists in this country who received cases from France after the shock and the acute symptoms had subsided, to exercise great care in the taking of the fields of vision and the construction of perimeter charts (though not with the McHardy perimeter), and follow the cases up as far as possible, keeping a record of their sequelæ, and in that way assist in making the investigations of Colonel Lister and Colonel Holmes of abiding value.

Colonel HOLMES briefly replied, remarking that as the steel helmets had only recently been issued to the British Army it was as yet too soon for conclusions to be drawn.

SECTION OF DERMATOLOGY.

Exhibition of Cases, Specimens, &c.

A MEETING of this section was held on March 16th, Dr. J. H. STOWERS, the President, being in the chair.

The PRESIDENT paid a warm tribute to Professor James Clarke White, whose death had deprived dermatology of one of its leaders. The deceased was professor of dermatology at Boston.

The following cases were shown:—

Dr. J. M. H. MACLEOD: A case for diagnosis. The patient, a woman aged 48, had a condition of Bilateral Facial Hemiatrophy. Eight years ago she had an eruption which was diagnosed as lupus erythematosus. The lesions disappeared quickly under treatment, but as each fresh lesion appeared and vanished it left an atrophic patch behind it.—Dr. W. KNOWSLEY SIBLEY considered that it was a case of sclerodermia, which had followed the cutaneous eruption.—Dr. F. PARKES WEBER thought it was an ordinary case

of bilateral facial hemiatrophy, possibly caused by the previous eruption, with which the PRESIDENT agreed.—Dr. S. E. DORE stated that he had had a similar case of atrophy which had followed lupus erythematosus.

Dr. G. PERNET: 1. A case of Staphylococcia in a girl with Xerodermia (staphylococcia *en nappe et en foyers à progression excentrique*).—Dr. DORE and Dr. H. G. ADAMSON considered it to be an ordinary case of infantile eczema.—Dr. PERNET objected to the diagnosis of eczema, as the lesions began as pustules, on a xerodermic skin, and not until the child was two years old.——2. Chancre on the lower lip.

Dr. E. G. GRAHAM LITTLE: Diffuse Papillomatosis (?) Acanthosis Nigricans. A woman, aged 52, had first of all some ulceration of the left leg, which was followed by an elephantiasic condition, with marked verrucose lesions around the ankle-joint.—Most of the members thought the condition was either of septic, syphilitic, or tuberculous origin.

Dr. MACLEOD: A painting of a very similar condition, which followed a septic ulcer.

Dr. A. EDDOWES: Acute Lupus Erythematosus with Nodular Necrotic Tuberculides of the Extremities. The patient was a woman, aged 27, with marked lupus erythematosus of the face and papules on the arms and legs —The section considered it to be a case of acute lupus erythematosus in which the prognosis was bad. It was the general impression that those cases ended fatally from a pneumococcic infection.

Dr. H. SPENCE (introduced by Mr. J. E. R. MCDONAGH): A Recurrent Syphilide simulating a Reinfection. The patient had a papulo-necrotic chancre in June, 1915, which was followed by neither inguinal adenitis nor by a rash. The sore healed up under four injections of "606." In January, 1916, another sore appeared on the penis which bore an exact resemblance to the original sore. There was also a lesion on the tongue, which simulated a primary sore. The other lesions were different in character.—Captain C. H. MILLS and Dr. PERNET thought the lesions on the penis and tongue were gummata.—Mr. MCDONAGH, who had seen the case originally, said he could not distinguish between the two sores on the penis and that the lesion on the tongue simulated a chancre.

Dr. J. L. BUNCH: Acute Sclerodermia with Sclerodactylia. The case was exhibited with the idea of eliciting the opinion of the section as to the advisability of treating the case by thyroid implantation. Implantation was only advised provided the patient showed an idiosyncrasy to small doses of thyroid. Its effect was considered to be temporary only.

Dr. ADAMSON: Microscopic slides of a unique case of Sweat Gland Tumour.

Dr. GRAHAM LITTLE also showed slides of the case he exhibited and of a tumour which had been removed from the vulva.

SECTION OF ELECTRO-THERAPEUTICS.

Experiments and Experiences with the Coolidge Tube.

AT the meeting held on March 17th under the presidency of Dr. W. IRONSIDE BRUCE, the section discussed Experiments and Experiences with the Coolidge Tube.

Dr. R. KNOX opened the discussion. He said that the Coolidge tube possessed, among other advantages over ordinary X ray tubes, the quality of extreme adaptability; it could be used continuously over long periods without risk of damage to the tube, with currents of any strength likely to be required for examinations. Four or five milliampères could be passed through it continuously for many years. Care must, however, be taken to protect both radiologist and patient, and sittings should be of as short a duration as possible. This tube was an instrument of precision in advance of anything of its kind yet produced. It could easily be adjusted for use in various parts of the body, and could be so arranged as to give off rays of varying penetrative power. For single-flash exposures it constituted the ideal tube. He had been carrying out a series of experiments, so far of an elementary character, with the object of ascertaining the best working conditions for the tube in radiography and radioscopy. The tube was altered from "soft" to considerable "hardness" in a few seconds. He hoped it would soon be possible to standardise radiographic exposures, and to make some advances in the measurement of X ray dosage. The chief merits of the tube were seen in therapeutic work; indeed, it would be difficult to conceive of any improvements likely to render it more efficient. Within reasonable safety limits, it could be used for many hours daily, and at the end of the day would continue its output of uniform radiations. One such tube used at the Cancer Hospital was worn out after 800 exposures; it was then repaired and still remained in use. The others used there had maintained their efficiency all through. Dr. Knox gave a full description of his investigations. The researches included both screened and unscreened rays, and their penetrating power into 4-inch thicknesses of beef. The tube made it possible to attack a deep-seated growth from all aspects, and thus as searching a treatment by X rays was possible as was obtained by embedding radium. The advent of this tube, said Dr. Knox, had opened up many interesting fields for experimental research, and he hoped that doctors would combine in an endeavour to standardise X ray exposures in therapeutic doses, a hope which the new tube seemed to justify.

Sir JAMES MACKENZIE DAVIDSON exhibited some interesting pin-hole radiograms, and showed from experiments the great need of the radiographer protecting himself when using the tube, as the rays were emitted from the back as well as the front.

Dr. G. HARRISON ORTON said he had used the Coolidge tube 14 months for deep therapy, and he did not think anybody who had employed it would revert to the ordinary X ray tube. It saved an enormous amount of time, and without forcing matters or overheating it was possible to turn a pastille in two minutes. The tube could always be adjusted to any required penetration, hence an exact repetition of a dose could be given. He found it particularly good for epilation, and by giving two separate 10*x* doses, with an interval between, dermatitis was avoided. In starting with a new Coolidge tube only about a 4·4 ampère current should be used until the anti-cathode became properly hot; otherwise there was apt to be sparking outside, and the tube was not absolutely constant until then. When in working order the tube required no cooling mechanism.

Dr. N. S. FINZI spoke of his clinical experiences with the tube. He was not sure that the tube yielded the best results in delicate detailed radioscopy, as compared with the ordinary tungsten target. For bismuth-meal radioscopy the Coolidge tube was ideal. For radio-therapy with the Coolidge he had been trying to get the exposure down to the shortest efficiency period. He had been able to epilate a whole scalp in five areas well within half an hour. Each exposure varied from 48 to 54 seconds. He agreed with Dr. Harrison Orton that no one who had used the Coolidge tube would care to go back to the ordinary tube. He preferred the Wehnelt brake to the mercury brake.

Dr. C. W. S. SABERTON spoke of a daily experience with the Coolidge tube for eight or nine months. He had not obtained such good negatives with this tube as with the ordinary X ray tube, but the type of rays emanated was uniform in the case of the former. In tinea cases his experience was not the same as Dr. Harrison Orton's; he required a larger dose to produce epilation. He advocated the measurement of dosage of X rays after filtration.

Dr. S. RUSS remarked that Professor Rutherford and his colleagues found they could not produce X rays of such short wave-length as the gamma rays of radium, the ratio being as 1·7 to 0·7. The difference in the radiographic results from ordinary tubes as compared with those of the Coolidge tube noticed by Dr. Finzi was probably due to the fact that the radiations came in one case from the whole stem of the anti-cathode. He felt that radiographers and physicists owed a great debt of gratitude to Mr. Coolidge for his invention, which he regarded as the most wonderful X ray tube which had ever been constructed, and that much more would be revealed by it in future.

Dr. KNOX briefly replied.

THE CHILD STUDY SOCIETY.—At a meeting of this society on March 16th Dr. Ernest Jones, discussing the Unconscious Mental Life of the Child, said three critical questions arose in such a study: (1) The extent of the justification in transferring the conclusions based on the abnormal to the normal; (2) the value of the examination of the adult mind as a basis for the study of the mind of the child; (3) the extent of the reliance on the psycho-analytic method of research. The last of these he did not deal with. In reference to the first question, the differences between the working of a normal and of a neurotic mind were only those of degree; disease added no new element, though the grouping of forces might be altered and the relative perspective

modified. On the second question, he said the saying "The child is father to the man" was taken seriously by the psycho-analyst. The unchanged form of the infantile mind was buried in the depth of the unconscious, constituting its characteristic. In the psycho-analytic sense the expression "unconscious" meant processes without the conscious *ego* but dynamically active in the production of external manifestations; those of high significance to the personality, and endowed with certain attributes, sharply distinguishing them from the familiar type of mental function. Many of the child's thoughts could not be communicated because he was unable even to formulate them. From the beginning the child was protected from painful stimuli by the immediate gratification of his wants. There were two clearly marked stages in mental development—the illusory and the actual—and these were always at work. The control of the primary system of thought by the secondary remained imperfect throughout life. In reference to the question of sexuality in children there existed a strong tendency to artificially restrict the conception of sexuality. It was ridiculous to suppose the sexual life to be non-existent until it took definite form at puberty; its earlier manifestations were tentative and preparatory. Later there came a process of refinement and the elimination of discarded elements. The unconscious was naturally unmoral, because it dated from a period preceding knowledge of good and evil, and had remained impervious to such knowledge. All that could be done was to modify the manifestations of the unconscious when they merged into the conscious. Much harm could be avoided by putting into practice some of the elementary principles of medical psychology; there was too much repression of tendencies, rather than a seeking to utilise those energies and tendencies for useful social purposes.

Reviews and Notices of Books.

Water Purification Plants and their Operation. By MILTON F. STEIN, Assoc.Mem.Am.Soc.C.E. New York: John Wiley and Sons; London: Chapman and Hall, Limited. 1915. Pp. 258. Price 10*s.* 6*d.* net.

THE author deals with the subject of water-supply from three points of view—that of the engineer, the chemist, and the bacteriologist. It is rare to find amongst water engineers the three qualifications, and such a combination of knowledge must be of great service to its owner and his employers. We may instance the advantage to a water engineer of being able to conduct bacteriological tests upon the spot. In his chapter upon this subject Mr. Stein points out that the making of bacterial tests requires considerable time, and for this reason it is often customary in small plants to send weekly or bi-weekly samples to some reliable testing laboratory for bacterial counts and coli determinations. He does not, however, recommend this plan, since it does not afford a continuous record of the bacterial efficiency of the filters, and between samplings the output may be high in bacteria for several days without the knowledge of the operator. Similarly valuable is it for the water engineer not only to be able to make chemical and physical examinations but to understand the significance of the results, and in this connexion Mr. Stein deals with many important questions in a manner which should be clear even to the non-technical reader. The chapters on types of purification plants, on filtration, coagulation, and sterilisation, evidence an intimate acquaintance with purifying methods and an appreciation of the watchfulness which is required to effect and to maintain the purity of the water-supply. The book is a valuable addition to the literature of an important subject and throws an interesting light on the up-to-date methods of the water engineer.

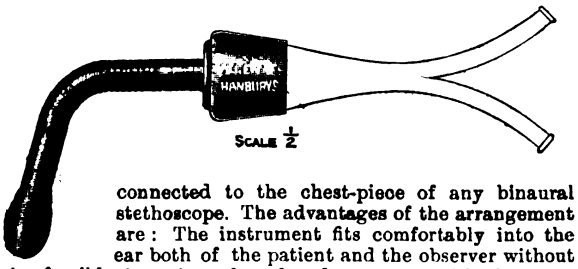
LIBRARY TABLE.

A Text-Book of Elementary Chemistry. By ALEXANDER SMITH, B.Sc. Edin., Ph.D. Munich. London: G. Bell and Sons, Limited; New York: The Century Co. 1915. Pp. 463. Price 5*s.* net.—The treatment of the subject is upon somewhat novel lines, as the author proposes to meet the needs of those who do not later continue the study of chemistry. He suggests that in the minds of such readers an interest in chemistry is best awakened by calling attention to materials and processes used in the household and in commerce. Such a book would have a limited value if at the same time the normal student was not considered, and so the plan includes a presentation of the elements of the science in a somewhat rationalised form, the principles underlying applications being carefully explained. The author makes the curious observation that in the general study of the subject the interests of the two sexes are in part different. Thus, he regards explosives, metallurgy, and the study of mortar and cement as of interest especially to males, while plastics, starch, sugar, soaps, and the nature, preparation, and digestion of foods make, he considers, special appeal to females. We much doubt the utility or rationality of this differentiation. The book gives a clear and homely account of the elements of the subject, and a good deal of really useful ground, practical and theoretical, is covered.——The same author has written *A Laboratory Outline of Elementary Chemistry* (same publishers, pp. 152, price 2*s.* net) as a companion to the text-book. His descriptions are in simple terms and he has, as far as possible, avoided the use of complicated apparatus and of rare or expensive chemical reagents. In short, the spirit of the "Text-book" is pursued in the "Laboratory Outline," which is a good example of clear practical teaching.

Physical Chemistry for Schools. By HENRY JOHN HORSTMAN FENTON, M.A., Sc.D., F.R.S. Cambridge: At the University Press. 1916. Pp. 215. Price 3*s.*6*d.* net.—In this acceptable little volume we have, in as simple terms as possible, the elementary principles of physical chemistry. We thoroughly approve of the author's plan to reduce mathematical expressions, when that can be done, and agree that students are often "liable to be scared away from the subject when it is presented in the more elaborate and mathematical form." And so, in accordance with this promise, we find an account of such phenomena as solution, osmotic pressure, adsorption, colloidal condition, catalysis, migration of ions, and so forth, which the reader will readily understand, provided he has some elementary knowledge of the subjects apart, i.e., chemistry and physics. We welcome this neat little compendium because of the growing importance of physical chemistry to medical science.

Food Analysis: Typical Methods and the Interpretation of Results. By A. G. WOODMAN. London and New York: McGraw-Hill Book Company (Inc.). 1915. Pp. 510. Price 12*s.* 6*d.* net.—This work will prove a useful guide to the student who requires to master the general principles involved in the analysis and examination of foods. The author has covered a fair amount of ground, and does not pretend to have exhausted the subject. He has chosen to deal with certain typical foods to illustrate, as he says, important methods or characteristic methods of food analysis. The aim of the book is to introduce general principles rather than to give counsel to the man in actual practice. Nevertheless, we have here the outlines of certain

progressive methods of analysis which will be of assistance to the consulting analyst. As examples, we may cite the chapters on the analysis of potable spirits (based largely on French and English work), on food colours and preservatives, and on cocoa and chocolate. The information is here largely based we feel sure, upon the author's laboratory experience, and that is a valuable feature of the book.



The Housing of the Working Classes Acts, 1890–1909, and the Housing Acts, 1914, Annotated and Explained together with the Rules, Regulations, Forms, and Instructions of the Local Government Board. By CHARLES E. ALLAN, M.A., LL.B., assisted by FRANCIS J. ALLAN, M.D. Edin., D.P.H. Fourth edition. London: Butterworth and Co., and Shaw and Sons. 1916. Pp. 493. Price 12*s.* 6*d.* net.—The preceding edition of this useful book has been for some time out of print. The work is so well known that a new edition requires little in the way of special commendation. Those who have to carry out the statutes and regulations brought together within its pages will find the information in convenient form, and will appreciate the care taken to avoid lengthy notes as well as all details which might render an everyday work of reference too bulky. It will be noted that Dr. F. J. Allan, an experienced medical officer of health in a metropolitan borough, assists in matters relating to practice. Such collaboration constitutes a very useful feature of the book, as for the carrying out of the Acts medical officers of health are so largely responsible. These officials, busy as they may have been before the war, are to-day likely to find their energies still more severely taxed. Anything that simplifies their present work is welcome, while this volume suggests important directions in which, when an honourable peace allows us, we may make good some of the defaults compelled by war.

A Pocket Medical Dictionary. By GEORGE M. GOULD, A.M., M.D. Seventh edition. London: H. K. Lewis and Co., Limited. Pp. 1003. Price 5*s.* net.—This is the seventh revised edition of a well-known pocket medical dictionary which contains 35,000 words. The claim of the author is that the dictionary gives the pronunciation and definition of the principal words used in connexion with, and in relation to, medicine; and the popularity which the work enjoys, as shown by its successive reissues, coupled with the favourable notices which each edition has received in the press, prove that the claim has been made good. Great condensation has necessarily been employed, for it is obvious that such a number of definitions, covering the vocabulary of half a dozen ancillary sciences, and all the procedures and abstract notions arising out of practical work or scientific theorising on those sciences, could not otherwise be included in any book that could reasonably be described by the word "Pocket." This condensation, however, has not resulted in inaccuracy, and on the whole has not made for vagueness. It is quite clear that the meaning of such words as, say, "catabolism" (Dr. Gould prefers a C) and "neurasthenia"—we select two words at hazard—cannot be defined in a line, and yet the notion given in the dictionary by the definition of these words is quite sufficient to meet the needs of anyone who should require to look out their meaning. Various tables of muscles, nerves, arteries, and the micro-organisms will be found useful, and the same may be said of the comparison of thermometric scales and of the dose tables compiled from authoritative works on materia medica.

New Inventions.

ADAPTER TO CONVERT BINAURAL STETHOSCOPE INTO OTOSCOPE.

THE simple contrivance for converting a binaural stethoscope into an otoscope here described will, I trust, prove as useful to others as it has been to myself. I have not seen a description of a similar instrument. The adapter, as will be seen from the illustration, consists of a vulcanite tube about four inches in length bent at a right angle in its centre. The aural end is like the termination of an ordinary otoscope, but the proximal end is attached to a soft rubber adapter, easily

connected to the chest-piece of any binaural stethoscope. The advantages of the arrangement are: The instrument fits comfortably into the ear both of the patient and the observer without the forcible insertion often found necessary with the monaural otoscope, but not at all pleasant to either of the persons concerned. The patient can hold the vulcanite tube in his ear and his attention is thus withdrawn from the catheter. The appliance has all the advantages of binaural hearing for the observer, and it is more compact than the ordinary type of otoscope, since extra tubing, in addition to that used with the stethoscope, is not required.

The adapter has been made by Messrs. Allen and Hanburys, Ltd., Wigmore-st., London, W., from whom it can be obtained.

Hove. NOEL ADLER, L.S.A.

LITERARY INTELLIGENCE.—The Physiological Society will very shortly issue a monthly journal, entitled "Physiological Abstracts," containing abstracts of papers in physiology, comparative physiology, biochemistry, and allied subjects, edited by Professor W. D. Halliburton, King's College, London, to whom reprints of papers should be sent. Those interested and desiring further information should communicate with Professor W. M. Bayliss, F.R.S., University College, London. The journal will be published by Messrs. H. K. Lewis and Co., Limited, 136, Gower-street, at an annual subscription of 25*s.*, post free.

HOSPITALS IN BIRMINGHAM.—The annual reports of the two large Birmingham hospitals appear simultaneously. According to the 136th annual report of the General Hospital the number of in-patients under treatment during the year 1915 was 5416, including 908 children under 12 years of age. The out-patients numbered 50,879. The ordinary expenditure was £34,051 11*s.* 7*d.* and the extraordinary £146 14*s.*, while the sum of £1132 14*s* 2*d.* was transferred to the Jaffray Branch Hospital account to meet the deficit of that institution. The total expenditure for the year was £35,330 19*s.* 9*d.* The deficit amounted to £13,213 1*s.* 11*d.* Nine members of the medical and surgical staff have been called up for service in the army, and this has added greatly to the work of the remaining members of the staff, who are practically all attached to military hospitals in Birmingham. A total of 75 former sisters and nurses are now serving in naval and military hospitals at home or abroad.—The seventy-fifth annual report of the Queen's Hospital shows that during the year 1915 3001 in-patients were treated and 24,397 out-patients. The income for the year was £12,527 and the expenditure £18,689, leaving a deficit of more than £6000. In common with other hospitals heavy demands have been made upon the services of the staff for military duties, but the work of the hospital has been carried on without interruption. Eleven members of the medical and surgical staff are attached to local military hospitals, and those who have received commissions or have enlisted include 13 from the medical staff, 31 medical students, and 27 of the nursing staff.

Reports and Analytical Records
FROM
THE LANCET LABORATORY.

INTRAMINE.

(THE BRITISH DRUG HOUSES, LIMITED, 20 TO 30, GRAHAM-STREET, CITY-ROAD, LONDON, E.C.)

THE chemo-therapy of intramine was described in THE LANCET of Jan. 29th, 1916. It was found to have a simpler composition than the arsenical types of syphilis remedies. It is a di-ortho body, and its chemical construction is described by its name, which is di-ortho-amido-thiobenzene. It is suggested that in early syphilis salvarsan should be administered first and then intramine, the order being reversed in late syphilis. The result of this treatment is spoken of most favourably. We have had submitted to us an ampoule of intramine, which contains a gramme of the substance emulsified in 10 c.c. of a cream. The intramine is administered by intramuscular injection in the form of a cream, and one advantage is that it does not oxidise on exposure to air, and, further, it is fluid at the body temperature. This interesting sulphur compound is a stable pale greenish-yellow substance not affected by the air, and while it is powerfully antiseptic it is non-toxic.

(1) HECTINE; (2) HECTARGYRE.

(THE ANGLO-FRENCH DRUG COMPANY, LIMITED (BRESILLON), GAMAGE BUILDINGS, HOLBORN, LONDON, E.C.)

1. The chief claim about hectine is that it can be successfully employed as an antisyphilitic and is far less poisonous than other arsenical compounds such as salvarsan and atoxyl, while stated to be equally effective. Its constitution is conveyed in its chemical name benzo-sulphone-para-amino-phenyl-arsenate of soda. It is a white crystalline substance readily soluble in water, which was first tried in syphilis in French clinics. In the treatment of syphilis it has been used in doses of 20 centigrammes daily dissolved in one cubic centimetre of water injected into the gluteal muscle. According to the results obtained it shows powerful anti-syphilitic properties. It is claimed to be less risky in employment than salvarsan. 2. Hectargyre is a mercurial salt of hectine which appears to combine with advantage the antisyphilitic properties of both mercury and the organic arsenic compounds. It is stated to be free from the objectionable effects of ordinary mercurial compounds. It is employed in syphilis with advantage in all its stages.

COGNAC BRANDY.

(GAUTIER FRÈRES, COGNAC. LONDON AGENCY: BROWN, GORE AND CO., 40, TRINITY-SQUARE, E.C.)

This liqueur brandy is described to be 20 years old, and we can well believe this since it possesses all the characteristics of a long-matured spirit. Further, the results of our analysis are consistent with those given by an old standard brandy produced in the Cognac district. The results of analysis were: Alcohol by volume, 46·59 per cent.; extractives, 1·10 per cent.; volatile acidity calculated as acetic acid, 0·03 per cent.; fixed acidity calculated as tartaric acid, 0·02 per cent.; mineral matter, *nil*. In regard to secondary products, the following were the results given in parts per 100,000 of absolute alcohol present: Aldehydes, 14·10; furfural, 2·10; ethers, 135. The flavour is unmistakably that of genuine brandy produced in the Charente district. It shows in particular a good etherial content, and there can be no question about its suitability for medicinal purposes.

STILL FRENCH MOSELLE.

(HATCH, MANSFIELD, AND CO., 47, PALL MALL, LONDON, S.W.)

We have been asked whether, from a medical point of view, the still French Moselles can be compared favourably with the German white wines. It has been customary on the part of many medical practitioners to recommend patients, in those cases where an alcoholic stimulant was deemed desirable, the German light wines, as showing a minimum of acidity, of sugar content and of alcoholic strength. The wine which was regarded as meeting these requirements was invariably a German white wine, but we find that the still French Moselles conform to the same standard remarkably closely. We append the analyses of two German white wines which are typical, and analyses also of three French still Moselles equally typical.

	German white wines.		French wines, still Moselles.		
	A	B	A	B	C
	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.
Alcohol by volume	9·86	10·30	10·73	10·30	10·73
Extractives	2·28	1·95	1·55	2·00	2·30
Sugar	0·19	0·18	0·17	0·23	0·10
Tartaric acid	0·57	0·67	0·54	0·67	0·71
Acetic acid	0·16	0·15	0·07	0·09	0·01
Mineral matter	0·22	0·16	0·14	0·15	0·20

The prices of the French Moselles are respectively—A, 21*s.*; B, 25*s.*; and C, 30*s.* per dozen. It will be seen that as regards alcoholic strength the differences are inappreciable, but when we come to the French Moselles the extractives in some instances give lower results than is the case in the German white wines. Considering sugar, the French Moselles, excepting one specimen, contained less. As to fixed acidity represented in tartaric acid, there is very little difference between the two classes of wines, but when we consider the volatile acidity represented in acetic acid we find that the French Moselles are distinctly superior to the German white wines. This is an important point, since to some extent the soundness of a wine rests upon the amount of volatile acid which it contains. The less present the better, and the French still Moselles are practically free from volatile acids. It follows that where a light non-acid wine, practically also free from sugar, is desired the still French Moselles may be recommended, and they are in no way inferior æsthetically to the German white wine. We think, indeed, that the flavour of some of the still French Moselles is more attractive and elegant than that of many of the German wines.

MALTED MILK TABLETS.

(HORLICK'S MALTED MILK COMPANY, SLOUGH, BUCKS.)

These tablets are a convenient form of the well-known preparation, malted milk. According to our analysis, Horlick's malted milk has the following composition: Moisture, 4·00 per cent.; total sugars, maltose and lactose, 52·83 per cent.; dextrin, 18·30 per cent.; protein, 13·05 per cent.; fat, 7·92 per cent.; and mineral matter, 3·90 per cent. Malted milk is clearly a nourishing article and it has the attractive flavour of malt. The method of preparation has evidently a certain solvent effect upon some of the constituents, since no less than 88 per cent. of the preparation of this malted milk is soluble in water. The tablets afford a very convenient and reliable form of food (containing all classes of nutritive elements) for the man engaged in a campaign on land, on sea, or in the air. The tablets are packed in a convenient tin and their diameter is somewhere between the size of a sixpenny and threepenny piece, while they are about an eighth of an inch thick. They are intended particularly as an emergency ration for troops engaged on a forced march. They seem to us well adapted for the purpose.

NON-ALCOHOLIC BEER (THREE SHELLS BRAND).

(THE NEW BREWERY SYNDICATE, LIMITED, 47, PALL MALL, LONDON, S.W.)

According to our analysis the claims in regard to this beer are well substantiated. It contains an amount of alcohol so low as to exempt it from the category of alcoholic beverages. The total amount of alcohol present in terms of proof spirit was just short of the limit laid down for temperance beverages—namely, 2 per cent. It is not often that beverages of this character can be said to be palatable, but this beer is a refreshing and attractive drink, delicately flavoured with hop, and evincing an unmistakable and pleasant malt flavour. Though brewed from malt and hops it contains very little extractive matters. The total amounted only to 1·10 per cent., while the sugar did not amount to more than 0·05 per cent., but this is balanced to some extent by the dextrin amounting to 0·87 per cent., including hop extractives. The acidity was inappreciable. The beer shows some nutritive properties, but we regard it favourably chiefly on account of its non-alcoholic and refreshing character and its delicate bitter flavour due to hops, and hops alone. There was present some salicylic acid, but in such small amount as to interfere in no degree with the wholesomeness of the beer. It is a genuine beer, and, as such, more interesting, we think, than most aerated drinks classed generally as non-alcoholic beverages.

THE LANCET.

LONDON: SATURDAY, APRIL 1, 1916.

The Enrolment of the Medical Profession.

THE conferences of representatives of the Local Medical War Committees which were arranged by the Central Medical War Committee to take place last week should, we think, have a distinctly valuable outcome, and the medical profession owes a debt of gratitude to the British Medical Association for having arranged (and paid for) a very practical method of dissipating some of the doubts and relieving some of the difficulties attendant upon the enrolling of the medical profession for military service. We published brief notes last week on the proceedings of the conferences at Leeds and London. This week we publish notes on those at Birmingham and Bristol, and the same general lesson may be drawn from the proceedings at all four gatherings—confidence in the policy and actions of the Central Medical War Committee has been promoted by a discussion of vexed questions. The widespread anxiety lest the Central Committee should override the judgment of Local Committees in the selection of names has also been allayed. It has in this way become obvious to audiences, who are themselves representative of these Local Committees, and therefore of the greater number of medical men concerned, that no alternative presents itself to voluntary enrolment save compulsion, in the event of the military authorities demanding further recruits from the medical profession. A stratum of the profession has now been reached, as Dr. ALFRED COX reminded the representatives of the Local Medical War Committees at the conference in Leeds, where great hardship may be experienced by the interchange of civil for military work, and the chances that those hardships, being intelligently recognised, will be removed as far as possible are greater, we think, under a system of voluntary enrolment than under one of compulsion, assuming that enrolment is effected by the bulk of those concerned.

The Central Medical War Committee has never concealed either from itself or from the constituency that the work of enrolment undertaken by the Committee is delicate in the extreme; the members of the Committee, or the majority of them, quite probably share the opinion which was expressed in this journal as soon as the overwhelmingly serious nature of the war was recognised, that a conscription of the medical profession would have given a fairer result. But the time has gone by when conscription can possess the virtues that it would have possessed originally, and although many members of the medical profession at the different conferences, notably at the gatherings in Birmingham and London, expressed a preference even at this date for compulsory enrolment, we think that the voluntary enrolment scheme is preferable if the difficulties in carrying it through are met fairly and squarely. A compulsory scheme applicable only to the medical profession has been deemed impossible, and other difficulties have never been made light of by any who understand the real situation of affairs, but the work of the Central Medical War Committee has not been rendered easier by masses of criticism, some of which may have been perfectly legitimate, but some of which has been ill-inspired, and some has had a suspect origin. The following train of thought is, for example, rather tortuous:—(1) The Army Medical Staff declares that a large number of officers are required in the Royal Army Medical Corps to meet growing armies and to make good depletions; (2) but the Army Medical Staff cannot know what is required because it has never consulted its Advisory Board; (3) therefore, when the Central Medical War Committee states that more medical men are and will be wanted for commissions in the Royal Army Medical Corps the Committee is misleading the medical profession. Yet that is a fair summary of the kind of way in which the work of the Committee and the behaviour of the Army Medical Staff have been criticised in letters to lay journals and in questions addressed in the House of Commons to the Under Secretary of State for War. There have been variants in the pattern of the argument, according as to whether the critic has been chiefly concerned in acclaiming the immorality of neglecting the Advisory Board, or in finding fault with the constitution of the Central Medical War Committee, or in criticising the way in which the officers of the Royal Army Medical Corps are employed when they have been recruited; but the assumption that there has been a great deal of mismanagement by everybody has been made so persistently that those who do not know the facts may have been impressed.

But lately the public has become aware of the unsubstantiality of the strictures; some of the complainants have been proved to be wrong in their facts, and others to have erred in their deductions, while a third class have come under strong suspicion of being inspired in what they have said, not so much by a desire to help in public affairs as by an itch to damage those at whose hands they believe themselves to have suffered material damage or personal slight. Categorical stories of lamentable breakdowns have been shown to be incorrect. Clear reasons for much of the plan adopted in the organisation of the Royal Army Medical Corps have been given. A story of an extraordinarily fine bill of health in an army of unprecedented numbers makes an absolute reply to those who consider that in the absence of an Advisory Board the authorities of the Army Medical Staff did nothing, or did only that which was wrong. The medical profession has already made great sacrifices with splendid results. Its members are being asked to meet a further demand on their services which many of them can ill meet. This is fully recognised. But if all show readiness to bear the burden, the weight should fall on the shoulders fittest to carry it. And it has now been definitely stated that unless a large proportion of the remaining available medical men under 45 enrol, the scheme of the Central Medical War Committee will not be proceeded with. That Committee is now reinforced by the formation of an Advisory Committee of the Royal College of Physicians of London and the Royal College of Surgeons of England, who will assist in the task of selecting the officers for the Royal Army Medical Corps.

Prescribing of Narcotic Drugs in the United States of America.

A YEAR ago particulars were given in THE LANCET[1] of the provisions of a measure, known as the Harrison Antinarcotic Law, to control the prescribing and selling of narcotic drugs which had just come into operation in the United States. The restrictions imposed by this Act were more severe than the regulations designed for the same purpose in any other country, and it was feared in some quarters that strict administration of the new law would be accompanied by such a large growth in the clandestine traffic in these drugs as would defeat the object with which the Act was promulgated. A year's experience, however, has demonstrated not only that the Act was capable of smooth administration, but that during the period in which it has been in force there has been no sensible increase in the smuggling of the class of drugs which the Act was designed to control. Some of the larger wholesale dealers in drugs are quoted as saying that their sales of drugs of this kind have been reduced by 70 to 80 per cent., and retail traders generally seem to be agreed that the amounts supplied to the public have been materially restricted. If then it is possible in a vast country like the United States, with its immense population, to limit the distribution of opium, morphine, and cocaine to the quantities required for legitimate medicinal purposes, how much more simple would it be to control the traffic in our own country.

One of the requirements of the American Act is that every person who prescribes or sells certain narcotic drugs shall be registered for that purpose and pay an annual registration fee of $1. This in itself is a considerable matter, since it affects something like a quarter of a million persons; an official report of the first year's administration shows that there have been registered in pursuance of the Act 140,000 medical practitioners, 42,000 dentists, 1100 veterinary surgeons, 48,000 druggists, and 400 manufacturing druggists. But the provisions of the measure do not stop at registration, this only being a means of keeping under supervision all the channels through which the narcotics are distributed. Pharmacists can only obtain supplies by ordering them on official forms, and they can only supply the drugs to medical practitioners who write their orders on similar forms. Prescriptions, which must bear the patient's name and address, can be only for a definite quantity, and have to be signed with the full name of the prescriber, whose address and registered number will also appear on the prescription. The pharmacist who dispenses the prescription is required to keep it for two years, and is prohibited under penalty from repeating the medicine except on the order of a fresh prescription. Although at times the observance of these precautions might occasion inconvenience, there has apparently been no noteworthy complaint, and the authorities acknowledge that they have received the ungrudging assistance of the medical profession in their attempt to stop the abuse of narcotic drugs. As must always happen when customs are suddenly altered, there have been cases of infringement due to negligence or want of comprehension of the regulations, and presumably there always will be occasional offences; but on the whole the Act has been well observed. The number of convictions that have been registered is 314, and a fair idea of the strict manner in which the Act is being enforced can be obtained from the fact that a registered person was fined for selling cocaine to a duly qualified medical practitioner whom he understood to be registered under the Act but was not, the court holding that the plea that the seller had good reason to believe that the purchaser was entitled to buy cocaine was worthless.

At present the provisions of the Act do not apply to preparations which contain only 2 grains of opium or ½ grain of morphine, or to preparations for external use which contain opium; but the authorities are considering the desirability of cancelling these exemptions, since they hold the view that the uncontrolled sale of even such preparations might serve to negative the good results to be expected from effectual enforcement of the new law. It is common knowledge that the opium, morphine, and cocaine habits had reached alarming proportions in the United States before this measure came into force, and since there is no evidence that the abuse of narcotic drugs in this country exists to any disturbing extent it is perhaps doubtful whether there is a need for the adoption of such stringent measures of repression in Great Britain. But the United States Legislature in enacting this law considered that they were bound to do so in order to carry out treaty obligations entered into by the States, in common with other governments; and if other parties to the treaty take as high a view of their obligations as do the United States, we may witness the enactment of replicas of this stringent law in many of the civilised countries of the world, when such time arrives as the nations have leisure to think of domestic legislation.

[1] THE LANCET, March 27th, 1915.

Annotations.

"Ne quid nimis."

MEDICAL DISEASES IN THE NEAR EAST.

AN official booklet has just been issued[1] containing in handy form memoranda on some of the diseases likely to be met with in the Near East, as well as some notes on sanitation. The diseases are arranged in alphabetical order, and under each are headings dealing with etiology, symptoms, prognosis, complications, diagnosis, differential diagnosis, prophylaxis, and treatment, with the addition in certain cases of a few lines on morbid anatomy. The booklet may therefore be regarded as a supplementary volume to a standard text-book of medicine containing the experience gained so far in the Near East brought carefully up to date. Although the chapters are anonymous, there is ample internal evidence that each has been written by an expert. To record their contents would be but to summarise what has appeared in the columns of our own and other professional journals during the last 18 months. Of special interest, however, are the short sentences relating to prevalence which commence each article. These might well be collected into a short preamble as follows:—

Cerebro-spinal fever: This disease has occurred at Salonica within recent years. In hot, dry, and sandy countries it is apt to appear in the season when dust-storms are prevalent.

Cholera: Happily at the time of writing no cases of cholera have been reported in the Mediterranean Expeditionary Force. With the advent of warm weather, however,

[1] Memoranda on Some Medical Diseases in the Mediterranean Area, with some Sanitary Notes. Wyman and Sons. 1916. Price 1s.

and the extension of the campaign to Bulgaria, it is more than likely that Asiatic cholera will appear in the war area.

Dengue: Occasionally breaks out in Egypt, has been reported from the Gallipoli Peninsula, probably visits the islands of the Ægean Sea, and is almost certainly found along the coasts of Greece, Bulgaria, and Turkey.

Diarrhœa: There were undoubtedly on the Gallipoli Peninsula and at Mudros many cases of acute diarrhœa unassociated with any form of dysentery or with flagellate infection.

Dysentery: Although happily the mortality caused by it has not been great, dysentery has been very prevalent amongst the troops serving in the Eastern Mediterranean area.

Malaria: A considerable number of cases of malaria, that most protean of all diseases, has occurred at Cape Helles and at Suvla Bay. Malaria is also endemic in and about Salonica.

Oriental sore, better known as cutaneous leishmaniasis, has occurred amongst the troops operating in Mesopotamia, and it is quite possible that cases may occur in the M.E.F., for the disease has been reported from Egypt, Arabia, Syria, Asia Minor, Turkey in Europe, and Greece.

Paratyphoid fever: Apart from dysentery and diarrhœa paratyphoid infections have undoubtedly accounted for most of the invalidings amongst men in the M.E.F. With the exception of troops which have served in India, B infections have been the more common, but there is no doubt that A infections have occurred in men who had been in contact with units from India.

Phlebotomus fever: This specific fever of short duration has a wide geographical distribution, and is known to occur in Egypt and on the Gallipoli Peninsula. It has especially affected the French at Cape Helles.

Plague: With the aggregation of ships in Eastern Mediterranean ports, the movement of Turkish and Russian troops from East to West, and the proximity of Egypt, plague may yet make its appearance in the war area.

Relapsing fever: So far there is no record of this disease having occurred among the troops of the Mediterranean Expeditionary Force, but with the extension of the campaign to the Balkans there is every likelihood that cases of what used to be called famine fever will occur. It has been recorded in the past from Salonica and Vodena.

Typhus fever: While there has been very little typhus fever amongst troops serving in the Mediterranean region, it may confidently be expected that the disease will be more in evidence throughout the winter and in the new area of hostilities.

Undulant fever is commonly known as Malta fever. It has a wide geographical distribution and has been known to occur throughout the eastern Mediterranean. Cases have cropped up amongst British troops operating in this area.

The list of diseases will be seen therefore to be a formidable one, and their prevalence in the Mediterranean area already considerable. But possibilities have been boldly faced, prophylactic measures carefully considered, and use made of the new preventive knowledge gained by recent experience, of which a digest is given in the chapters on Insect Pests and Sanitary Notes. The booklet will naturally form the vade-mecum of the Royal Army Medical Corps officer; but over and above this it will be impossible for any medical man within or without the Services to consider himself well informed without reading, marking, learning, and inwardly digesting this official handbook.

THE GALE AND A LESSON.

IT is many years since the elements have raged in this country with such fury as on the evening of March 28th, when a wind velocity of 47 miles an hour was recorded at Greenwich. Trees and telegraph posts were blown down all over the country, long-distance trains ceased to arrive at the London termini, and snow drifted in places many feet deep. Already several deaths are reported from being blown over in perilous situations, from various accidents, and from exposure on the hills. This list will probably be higher when messages again pass over the reinstated telegraph wires, and for every death from exposure scores will have suffered more or less permanently in health from the same cause. In nearly all cases where this happens the sufferer will be found to have been insufficiently or unsuitably clad. During the last 18 months millions of men have been clothed at the expense of the State in woollen garments of such texture and thickness that soaking should be impossible, and in footgear through which water percolates with difficulty. Under these conditions the conduction of heat away from the body seldom reaches a dangerous degree. It is surely time that the civilian population rendered themselves similarly immune to meteorological conditions in the winter and spring. It is a mistake to suppose that this requires heavy or thick clothing, it is largely a question of texture and uniformity. Now that fashion has relaxed her claims, the opportunity should be taken to discard paper shoes, gossamer stockings and blouses, and similar follies. When the claims are again heard, some at least will refuse to risk their lives for appearances that are often unsightly.

TORULA INFECTION IN MAN.

THE latest issued of the series of monographs from the Rockefeller Institute for Medical Research is concerned with a group of cases characterised by chronic lesions of the central nervous system, with clinical symptoms suggestive of cerebral tumour, produced by an organism belonging to the torula group. The authors of the monograph, Dr. James L. Stoddard and Dr. Elliott C. Cutler, of the Peter Bent Brigham Hospital at Boston, Mass., describe two cases in which the clinical symptoms indicated such signs of cerebral tumour as to lead to decompression or exploratory operation, but the pathological examination in each case proved the complete absence of tumour. Lesions were found, however, which fully explained the clinical symptoms and physical signs. Enormous numbers of organisms having many points of resemblance to those of blastomycosis occurred in all of the lesions in such a manner as to leave no doubt of their causal relations. The neurologist is familiar with cases to which the unsatisfactory diagnosis of pseudo-tumour has been attached, in which the accepted symptoms and signs of cerebral tumour—viz., headache, giddiness, vomiting, and optic neuritis, accompanied or not by more definite and even localising signs—are found at operation or at necropsy to have been caused by some totally distinct condition. Some reported cases, possibly incompletely examined, have remained more or less of a mystery. In the first of the two cases recorded in this monograph a woman aged 42 entered hospital on account of headaches, failing vision, giddiness, nausea and vomiting, diplopia, unsteady gait, difficulty in finding words, and disorientation. During the first two weeks of the illness the temperature ranged from 98° to 102° F. On examination double optic neuritis was present, a diagnosis of increased intracranial pressure, without localising signs, was made, and a right subtemporal decompression was practised. On incising the dura the brain appeared tense, and there was excess of fluid in the subdural and subarachnoid spaces. The patient died some ten days later after developing pneumonia and relapsing into a stuporose condition. At the necropsy a subacute or chronic meningo-encephalitis was found, with multiple foci of infection in the cerebellum, cerebral cortex, and basal ganglia. Microscopically enormous numbers of spherical organisms, of varying size, with a definite wall, were everywhere found in the lesions. Neuroglial reaction was present in the immediate vicinity of the lesions, and there was slight diffuse degeneration of ganglion cells and

myelin sheaths. In regard to the lesions themselves, many revealed areas of necrosis or caseation, such as are seen in tuberculosis, and giant cells were noted in some numbers, with oval or spherical nuclei arranged peripherally or centrally. There can be no doubt in the writers' opinion that the organism is a torula, and the features of the case are analogous, clinically and pathologically, to those of cases collected from the literature. The symptomatology of these closely resembles the clinical picture of intracranial neoplasm. A chronic, slowly progressing inflammatory process, situated in such a way as to interfere with the passage of cerebro-spinal fluid and occasion internal hydrocephalus, or leading to the formation of masses of parasites in various parts of the cerebrum or cerebellum, results in the development of symptoms of raised intracranial tension which it may be impossible to distinguish from the pressure effects of a brain tumour. There are similarities also, as is apparent, with other chronic infective conditions of the central nervous system, such as syphilis. A considerable portion of the monograph is taken up with a valuable investigation into and differential classification of the diseases formerly called blastomycosis. As a result of much personal experimental research, succinctly summarised in the monograph, the authors publish an elaborate table of differential points between torula infection, oidiomycosis (usually termed blastomycosis), and coccidioidal granuloma. In the general discussion which concludes the paper reference is made to the fact that torulæ were proved years ago by several observers to have marked pathogenic action in animals, with frequent production of brain lesions. How common this type of infection is in man is unknown, but many facts indicate the possibility of its being frequently present without recognition. The organism is probably not always very pathogenic in man, and lesions may be recovered from. In the healed stage the lesions are those of a slightly atypical tuberculosis, and the condition may thus be passed over. Experimental lesions in animals are sometimes quite indistinguishable from miliary tubercles without caseation. The general conclusions of a suggestive and valuable piece of work are that the factors which will aid the recognition of torula infection consist of: Discovery of early lesions in internal organs before the parasite is destroyed; realisation of the finer points of difference from tuberculosis; complete microscopical brain examination; cultures, especially on carbohydrate media at room temperature; and injections of fluids and cultures into white rats intraperitoneally, with microscopical examination especially of the brain.

EFFECT OF FATIGUE ON GASTRO-INTESTINAL ACTIVITY.

Dr. Ludwig Kast, of New York, has investigated the effects of fatigue on 54 patients and healthy subjects to test the motor power of the stomach and intestines. The stomach-pump and X rays were employed; to determine the time of elimination of the intestinal contents carmine was used, a standard test diet being given for a number of days. By taking the average, it was determined how long it took the stomach, and separately, how long it took the intestines, to propel the given amount of food. During the period of the tests the amount of physical activity was regulated and the mental activity approximately limited. Without any change of diet or of mental activity, the physical activity was markedly increased or decreased, and the effects of the same upon the evacuating power of the stomach or intestines observed. At other times, without change in the diet or the amount of physical exercise, the amount of mental efforts was markedly increased or decreased and the effects observed. It appears that the healthy individual showed very little variation as regards the evacuating power of the stomach or intestines as long as the physical exercise was not excessive. Mental efforts had no perceptible effect. In patients with moderate degree of atony and splanchnoptosis the evacuating power of the stomach and intestines decreased in direct proportion to the amount of mental and physical exertion. Physical exertion had the same effect in such individuals if the patient was kept in a horizontal position during these exercises and during the period of observation in order to eliminate the effect of splanchnoptosis in the erect position. In patients who clinically appeared susceptible to the effects of fatigue mental exertion was more marked in its delaying effect than physical exertion.

RELATION OF HIGH ARTERIAL TENSION TO ALCOHOL.

MUCH difference of opinion exists as to the part played by alcohol in the causation of high arterial tension, arterio-sclerosis, and interstitial nephritis. After carefully studying the question Lancereaux, the well-known French clinician, stated that alcohol does not favour the production of arterio-sclerosis. At the Académie de Médecine of Paris M. Camille Lian has reported an interesting investigation which his position as surgeon to a Territorial regiment enabled him to make. With the Pachon-Lian sphygmometer he took the blood pressures in the afternoon of 150 men, all aged 42 or 43 years. Without consulting the results he investigated their habits as to alcohol and divided them into four classes: 1. Sober, those who took less than a litre of wine daily and no spirits. (A litre of cider or beer was considered equivalent to half a litre of wine.) 2. Medium drinkers, those who took 1 to 1½ litres of wine daily and no spirits. 3. Great drinkers, those who took 2 to 2½ litres of wine or a smaller quantity and one or two *apéritifs* or *petits verres*. 4. Very great drinkers, those who took at least 3 litres of wine or a smaller quantity and four to six *apéritifs* or *petits verres*. The number of each group in whom the blood pressure was above normal—that is, the maximum pressure above 15 cm. of mercury and the minimum above 10—was then noted. The results were as follows: Sober, 16 men, blood pressure above normal 1 (6·25 per cent.); medium drinkers, 53 men, blood pressures above normal 4 (7·5 per cent.); great drinkers, 57 men, blood pressures above normal 10 (17·5 per cent.); very great drinkers, 24 men, blood pressures above normal 6 (25 per cent.). The greater frequency of high blood pressure as the consumption of alcohol increased showed that this substance was an important factor in causation. It might be objected that the increased pressure may have been due to other causes. But in such a number of subjects it was to be expected that these causes would be distributed without marked difference amongst the various groups. Moreover, the men were examined for stigmata of syphilis and questioned as to other infections and intoxications. After eliminating the cases in which another factor could have been in play it was found that the percentages of high pressure in the four groups were not sensibly altered.

HEALTH OF THE POST OFFICE STAFF.

IN his report for the year 1914–15 the Postmaster-General states that the health of the staff has again been satisfactory. The average sick-rate of the established staff during the year ended Dec. 31st, 1914, was 7·5 days for men and 11 days for women, and of the unestablished staff 4·8 days for men and 5·7 for women. The deaths through causes other than war recorded through the year show an annual death-rate of 3·3 per 1000 for men and 1·2 for women on the established staff. Of the 319 men who died the average age on death was 41, and the average length of service 17 years. Of the 38 women who died the average age was 32 and the length of service 10 years. 680 men and 161 women retired on account of ill-health at an average age in the case of men of 46, and in the case of women 35, the average length of service being in the case of men 24 years, and in the case of women 15 years. In 1912 the proportion of deaths and retirements from tuberculous diseases to deaths from all causes and retirements from ill-health in the Post Office was 14·5 per cent.: it appears from the Registrar-General's annual return for 1912 that in the case of persons in the United Kingdom between the ages of 15 and 65 the proportion of deaths from tuberculous diseases to deaths from all causes was 20·7 per cent. In 72 per cent. of the cases of tuberculosis occurring during 1914 there was a history either of previous tuberculous disease in the family or of previous illness predisposing to tuberculosis in the patient. The number of fresh cases arising in 1914 showed a substantial decrease as compared with those of the foregoing year. Every facility is granted to Post Office servants suffering from tuberculosis to obtain sanatorium treatment where a reasonable probability of recovery exists. Of the cases occurring during 1914, which were completed before the end of the year, about 35 per cent. of those who received sanatorium treatment were able to resume duty as compared with 16 per cent. in the case of those who did not receive such treatment. An examination of the cases of neurasthenia occurring during 1914 showed that in the majority of cases the disease was attributable to physical causes or to domestic troubles.

THE OPERATIVE TREATMENT OF OSTEO-ARTHRITIS.

THE main cause of the disability met with in cases of osteo-arthritis is the lipping of the edges of the articular surfaces of the bones entering into the affected joints. From time to time surgeons have removed one or more nodules of bone from such joints, but it has been left for Mr. W. I. de C. Wheeler to perform a definite operation for the purpose of relieving the disability of sufferers from this disease. He operated, as mentioned in last week's issue of THE LANCET (p. 678), on a patient who had been crippled for seven years by osteo-arthritis. He removed all the newly formed bone from the left knee and from the right hip, with the result that the patient, who before the operation had been able to walk only with the help of crutches, no longer needed their assistance, and further walking caused no pain. Mr. Wheeler is to be congratulated on the success of his operation. Unfortunately, the report does not give the age of the patient, though we gather from his remarks that the patient had not passed middle age. Be this as it may, we consider that the operation can reasonably be tried in suitable cases, for the relief of pain and of the lack of mobility which osteo-arthritis entails is worth more than the little risk attending such an operation. On one point we disagree with Mr. Wheeler, and that is on the name chosen for his operation. He has called it cheilotomy, and this obviously means "cutting the lip," and the name, no doubt, refers to the removal of the lipping of the bones, but we would urge him to endeavour to find a more suitable appellation for the operation he has devised, for such a name as cheilotomy should be reserved for an operation on the lips.

DR. GIORGIO MENINI.

THE death occurred on March 6th of Giorgio Menini, perhaps the ablest pupil of Grocco in the Istituto di Studi Superiori at Florence. A brilliant academic career led up to his speedy promotion as "Libero Docente" in pathology and as director of the clinical laboratory of the Santa Maria Nuova Hospital. State hygiene was another field in which he showed exceptional proficiency, insomuch that the Government charged him, in that interest, with a special mission, first to the Island of Sardinia, and then, during the Balkan War, to Albania. Among the Mussulman population he soon became a general favourite, his work in sanitary rehabilitation winning their gratitude and their confidence, and overcoming the distrust with which Christian intervention is received, often resented, by the "Faithful." Throughout the whole Sanjacate of Berat the presence of "Menini Italiano" was not only a medical but a political force. Returning to his post in Florence, he showed signs of impaired health, but no inducement or friendly admonition could wean him from professional duty, beloved as he was by his students and in constant request as a consultant by an ever-increasing *clientèle*. Within the last few days his resisting power seemed to relax with ominous rapidity, and he died while not yet 40 years of age, leaving behind him a sense of loss in which the profession and the public participate hardly less than his colleagues and immediate friends.

AT the Royal Society of Medicine on Thursday, April 13th, at 5 P.M., Mr. J. E. R. McDonagh will open a discussion on the Rationale and Practice of Chemo-Therapy, to which leading chemists have been invited.

UNIVERSITY OF LONDON OFFICERS TRAINING CORPS.—The Military Education Committee which was appointed to deal with the administration of the University of London Contingent of the Officers Training Corps shows by its seventh annual report that on Dec. 31st, 1915, the establishment included a medical unit consisting of four sections of a field ambulance. The numerical strength of this unit is owing to war conditions not given, but during the training year ending Sept. 30th, 1915, the cadets numbered 415, of whom 95 proceeded to commissions. During the year the following officers joined the medical unit: Major G. E. Gask, Captain W. Gilliatt, Captain R. D. Maxwell, Lieutenant J. H. Ryffel, and Second-Lieutenant A. Rodd. In an appendix to the report the list of former officers of the University who have fallen in the war includes the name of Captain G. C. McKay Mathison, A.A.M.C., and in the list of former cadets who have been killed are the names of R. Fazan, F. E. Harger, T. S. Lukis, M. Pern, and W. R. Pryn. As a consequence of the Military Service Act the Officers Training Corps of the University of London is now open only to students and other persons desirous of training for commissions who are under the age of 19 years. Application for enrolment should be made to the Adjutant, 46, Russell-square, W.C.

FOOD ECONOMICS IN RELATION TO THE WAR.

BY HARRY CAMPBELL, M.D. LOND., F.R.C.P. LOND.,
PHYSICIAN TO THE WEST END HOSPITAL, LONDON.

II.[1]

Foods the Home-supply of Which it is Most Desirable to Amplify.

BESIDES wheat, which the Government is wisely encouraging the farmers to grow more of, we should seek to increase the output of peas and potatoes. These all possess the double virtue of being highly nutritious and admitting of long storage. Peas, which contain a high percentage of protein, are almost as nutritious in the dried state as when fresh. There would be no difficulty in increasing their output enormously. In 1913 the acreage of peas was only 161,121, as against 1,184,857 of potatoes and 3,983,448 of oats.

The subject of market-gardening requires careful consideration. Green vegetables are essential and a modicum of fruit is desirable, but the cultivation in large quantities of such vegetables as asparagus and tomatoes, and such fruits as grapes and strawberries, should not be encouraged. It entails too much money and labour, and is only justifiable where there has already been an initial outlay upon them. The question whether acorns, beech-nuts, and horse-chestnuts might be used for human food is worth considering. An agreeable flour can be made from acorns by maceration and subsequent drying and grinding, as has long been known to the Californians and other primitive peoples. In any case, all the available acorns should be gathered, for they are a valuable food for pigs and sheep. Horse-chestnuts can be made into a suitable food for animals. Like acorns, they contain some 40 per cent. of oil, and yet thousands of tons of these valuable seeds have recently been allowed to rot.

Coming now to live stock, the breeding of pigs should certainly be encouraged, and I see no reason why we should not have as large a proportion of these animals as Germany has. During the last 40 years the stock of pigs in that country has been increased from 7,000,000 to 20,000,000, while in England the number has recently fallen by nearly a million, and now totals little more than 3,000,000. Our annual expenditure on imported bacon, ham, pork, and lard amounts to about £27,000,000 sterling. Pig-farming has the advantage over sheep and cattle-farming in that the pig needs little more ground than the stye it occupies, although, of course, it uses up the products of the soil, notably in the shape of barley-meal, which, unfortunately, at the present time is considerably above the normal price. An immense amount of food suitable for pigs, which should go to the swill-tub, is lost in this country, owing to the lack of organised methods of collecting it in the towns. One of the special virtues of the flesh of the pig is that it lends itself so well to the processes of curing, and can be so conveniently stored.

Dairy-farming should be encouraged chiefly for the purpose of increasing the home-supply of butter and cheese, which we annually import to the value of about £24,000,000 and £7,000,000 sterling respectively.

Poultry-farming has met with little success in this country. Nevertheless it should be developed, chiefly, I think, with the object of increasing the output of eggs, which we import to the value of some £9,000,000 sterling annually. Eggs admit of ready storage. The chief expense of poultry-farming lies in the large quantity of corn required, but while it is economical to convert corn into eggs it is doubtfully economical to turn it into mature chicken fit for the table. I therefore suggest that the young cockerels should be killed off early, say when they reach the size of a partridge, at which stage they furnish the acceptable dish known as *poussin*.

It is hardly necessary to say that pheasant rearing is, from the point of view of food economy, highly wasteful, and only justifiable on a very limited scale.

Food Consumption.

It is our clear duty at the present time to exercise rigid economy in the matter of food consumption. By reducing the expenditure on food by £1 yearly per head (i.e., less than ¾*d.* a day and rather more than 4½*d.* a week) we should effect an annual saving of more than £45,000,000—i.e., an amount more than sufficient to pay the interest at 4½ per cent. on a loan of £1,000,000,000 sterling. I believe that by properly regulating the kind and quantity of food consumed and by minimising wastage such a saving is possible, and this not only without any sacrifice of the national health but with an actual improvement of it. Great economy could also be effected by reducing the consumption of alcohol. In 1915 the national drink bill was something more than £164,000,000. It is true that much of this huge sum goes back to the country as duty, but more than three-fourths of it represents a dead loss of wealth. To advise the nation to save this great sum is, I fear, a counsel of perfection. Nevertheless it would be a grand thing if we could rise to the occasion and all agree to abstain from alcoholic drinks during the period of the war. In this way we should, at a stroke, save the consumption of the thousands of tons of grain (70,000,000 bushels annually) employed in the manufacture of beer and spirits, divert a vast amount of energy now employed in brewery, distillery, and drink shop into more profitable channels, and improve the health and raise the morale of the nation.

There are at least four ways of reducing the consumption of food: (1) By preparing the food in the most economical way; (2) by minimising waste; (3) by selecting the right kinds of food and in the right proportions; and (4) by limiting to a sufficiency the quantity of food consumed. It is clearly of the utmost importance to prepare food in the most economical way and to prevent unnecessary waste. The best means of effecting these ends are receiving considerable attention just now, and there is no need for me to deal with this subject. Considerable economy may be effected by choosing the right kinds of food and taking them in the right proportions. In order to reduce to a minimum the amount of food required, the protein, saccharide,[2] and fat need to be proportioned somewhat as follows: fat, 1; protein, 2·5; saccharide, 10. If the food consists chiefly of bread and potatoes, then in order to provide the necessary quantity of protein an excess of saccharide has to be consumed. If, again, it is mainly of the animal variety, the needful supply of saccharide can only be obtained at the expense of an excess of protein. The most common error in this country in apportioning these three great classes of foodstuffs is to

[1] Article No. I. was published in THE LANCET of March 25th, p. 686.

[2] By *saccharide* I mean *carbohydrate*.

consume an excess of saccharide in the shape of bread, puddings, potatoes, and sugar, and too little fat. This is especially the case with the poor.

Man a Mixed Feeder.

The question how far man is adapted for animal and how far for vegetable food is one on which the public should be correctly informed. Man is neither purely carnivorous nor purely vegetarian: he is a mixed feeder. Some contend that he is by nature purely vegetarian, and that a strict vegetarian diet is more conducive to health than a mixed, and a vegetarian enthusiast has recently suggested that the present would be a good time for the nation to exclude animal food altogether, on the ground that the food production of this country could be greatly increased if the farmer ceased to breed cattle, sheep, and pigs, and devoted himself exclusively to the cultivation of vegetable food—above all, of the cereals. While admitting that every effort should at once be made to increase the home supply of wheat, we must be careful to avoid the sentimental error of supposing that man is by nature strictly vegetarian, no matter how anxious we may be to adopt a diet which does not involve the rearing of animals for slaughter. The fact is, as I have elsewhere endeavoured to show,[3] it was by virtue of persistent slaughter, continued through many thousands of centuries, that man evolved from the ape—that he grew into a being endowed with speech and reason and with aspirations beyond the grave. I have no doubt that it was the attraction of animal food which led the prehuman ape to abandon the forest for the plains, and that the conditions entailed by hunting were the chief factors in determining his evolution into man.

Other factors also operated. Intertribal warfare was, I believe, one of these, and I mention it here because it bears upon a question of burning interest at the present time—the influence of warfare on evolution. All are agreed that whatever influence modern warfare may have in bracing up and stimulating a nation to meet difficulties, it has a disastrous effect eugenically, seeing that it causes an elimination of the physically fittest, and in a country like our own, which adopts the voluntary system, of the bravest, most spirited, and most conscientious—in short, of those with the most grit. A strong argument, by the way, against a strictly voluntary system. While, however, modern warfare is a grave hindrance to evolution, I believe that primitive warfare played a not inconsiderable part in furthering it, notably in the psychic sphere, for it was a warfare of tribe against tribe, and its general effect was to cause a survival of the most brainy, most courageous, and most energetic tribes at the expense of their less gifted antagonists. This process continuing through many thousands of years, must have led to a steady evolution of the qualities which secured victory. This is a further illustration of my contention that man has evolved through slaughter. Strange, indeed, it is that he—the roof and crown of things—should have fought his way upward by bloodshed, and that from the standpoint of evolution modern warfare should have an effect the exact opposite of the old-time warfare of tribe against tribe.

Let us now consider the various types of animal and vegetable food consumed in this country.

[3] Man's Mental Evolution, Past and Future, THE LANCET, May 3rd (p. 1260), 10th (p. 1331), 17th (p. 1408), and 24th (p. 1473), 1913.

Animal Foods.

The following are our chief animal foods:—Beef, veal, milk (cheese, butter), mutton, lamb; pork (lard), bacon, ham; rabbit, game; poultry, eggs; fish. The value in millions sterling of imported animal food for the year 1913 was as follows:—Bacon and ham, 20·4; beef, 16·1; mutton, 10·9; pork, 1·6; butter, 24·3; cheese, 7·4; eggs, 9·5; fish, 4·8; lard, 5·5; margarine, 0·39. Of the various kinds of animal food rabbit and fish are the most economical, meat the most expensive. It occurs to me that a considerable wastage of fish might be prevented if more of it were smoked, salted, or otherwise cured. Surely no particle of edible fish should be thrown away. Those who are not risking their lives at the front must learn not to be over fastidious about their food. The importance of reducing the consumption of meat is generally acknowledged. It is well to remember that dislike of fat may lead to considerable waste by increasing the scraps left on the plate. A person who dislikes mutton fat, for instance, may not extract from a mutton chop one half its nutrient value. Such wasteful meat eaters should before all others restrict their meat diet at the present time. Fat constitutes a most important item of our food, and none of it should be wasted. Nearly all who cannot eat the fat in a cut off a joint relish dripping in cakes or simply spread on bread, as well as beef suet in puddings. In the case of families thus inclined as much of the fat of the meat as possible should be used as dripping or suet. This is important because the dietary of many people, notably children, is apt to be deficient in fat. One of the virtues of the flesh of the pig is the large amount of fat it contains. Many who cannot eat fat meat relish fat ham and bacon and lard worked up in cakes.

Milk.—It is very generally but erroneously believed that the child, as distinguished from the babe, needs milk and would suffer greatly if the supply of dairy milk suddenly failed. As a matter of fact, dairy milk has injured children far more than it has profited them. Milk, affording as it does a peculiarly favourable soil for the growth of disease germs, has carried disease and death to hecatombs of children. Not only has it been the chief means of conveying tuberculosis to them, but it has further acted injuriously by favouring the consumption of soft, pappy foods, such as sops and milk puddings, on the evils of which I shall have occasion to dwell later. It goes without saying that the infant, like the young of other mammals, requires milk for the first period of its life, and that the proper milk for it is its own mother's. When this fails, as it sometimes does (mainly, however, owing to unhealthy upbringing), milk from some other mammal, such as the cow or goat, has to be substituted, and we must, I suppose, gratefully acknowledge the service which non-human milk has rendered in enabling us to rear infants artificially. But even in this sphere it has not proved an unmixed blessing, in that it affords an excuse to unwilling mothers not to nurse their infants and not to regulate their lives in a way calculated to develop the nursing function. While, however, the infant needs milk of some kind during the first nine or ten months of life, it does *not need any after that period.* It is strange how the belief to the contrary has arisen. Why should the young of man any more than the young of any other mammal require milk after it has left the breast? It is only since man first domesticated the cow and the goat,

and this from the point of view of his evolution was but as yesterday, that he has been supplied with any milk other than human, and it is absurd to suppose that before that time his health suffered from the lack of cow's or goat's milk. To this day many pre-agricultural tribes are without any. When Australia was discovered, and this was only a few hundred years ago, the natives had not cultivated one square foot of that great continent; their only domesticated animal was a half-wild dog, and not one of them had ever tasted any other milk than woman's. Nevertheless, they were a vigorous healthy race with magnificent teeth. I mention this latter fact because I have heard it seriously suggested that the lack of an adequate supply of dairy milk is the chief cause of bad teeth among the poor of this country.

My point is not that dairy milk is a useless food for man, but merely that it is not essential to him after the nursing period. Its chief value to the human race, so it seems to me, is as a source of butter and cheese, two highly concentrated and agreeable foods, admitting of prolonged storage: not only cheese but salt butter may be kept for many months. For both these articles we are largely dependent upon foreign supplies. In 1913 we imported butter to the value of £24,000,000, and cheese to the value of £7,000,000. Would it not be wise, during the period of the war at least, to reduce our consumption of milk to a minimum and to make as much butter and cheese as possible, especially the latter, on account of the large amount of protein it contains? Plain cheeses, such as Cheddar and Cheshire, should be made in preference to the richer kinds, such as Stilton, which serve rather as savouries than as sources of nutriment. Some milk is required for infants and invalids; some also may be reserved as a flavouring for tea. Save in the case of invalids the quantity used for cooking (e.g., for milk puddings, cabinet pudding, batter pudding, Yorkshire pudding, trifle, and blanc-mange) should be reduced to a minimum. Puddings made of flour and suet, such as suet dumplings, roly-poly, and fruit or meat puddings, boiled or steamed, are, if anything, more wholesome than those containing milk, butter, and eggs.

Vegetable Foods.

Our vegetable foods may be classified as follows:—The cereals: wheaten flour (macaroni, vermicelli, semolina), oatmeal, rice, maize. Starch: sago, tapioca, arrowroot. Sugar. Vegetables: cooked (potatoes, peas, greens, &c.), and uncooked (salads). Fruits: luscious (apples, strawberries, grapes, &c.) and nuts. Beverages: tea, coffee, cocoa.

The cereals.—Of the various cereals consumed in this country wheat (wheaten flour), oats (oatmeal), and rice occupy the first place. Oatmeal is the most nutritious, containing as it does even more protein than wheat and considerably more fat. Rice is the least nutritious of the three, and inasmuch as it is for the most part consumed in a soft or even pappy form which does not invite mastication, and is moreover wholly imported into this country, we could very well dispense with it. Oatmeal porridge is a valuable food, but like rice (as served in this country at least) it does not conduce to mastication. Further, it uses up a lot of milk which might be better employed for making cheese and butter. We should therefore take the precaution to chew our porridge carefully and to be sparing in our use of milk with it. Oatmeal biscuits constitute a valuable food, and favour efficient mastication. Wheat has a double advantage over other cereals—it has the most delicate flavour and contains a large amount of gluten. Consequently, wheaten flour, unlike the flour of other cereals, is readily kneadable and can therefore be made into bread, macaroni, vermicelli, pastry, and all sorts of puddings and cakes. At the present time we need to exercise the utmost economy in our use of wheaten flour, and it should be reserved almost entirely for making bread and boiled suet "crust" (suet pudding, fruit pudding, meat pudding). Plain home-made cake and plain biscuits may be made in moderation, and even plain pastry; but rich pastry and fancy cakes, and such articles as buns, scones, tea-cakes, all of which are abundantly displayed in our confectionery shops, should be abandoned.

Bread has been aptly described as the staff of life. A good hunch of crusty bread, thoroughly chewed, with butter and cheese or fat bacon, followed by a little raw fruit, such as an apple, constitutes an ideal meal. Not only does it provide the needful nutritive ingredients, but it gives the teeth and salivary glands ample work, and leaves the mouth in a "hygienic" state. We have heard a great deal lately of potato bread. This is quite a pleasant food and it is a good plan to make it of cooked potatoes which might otherwise be wasted.

Starch.—Tapioca, sago, and arrowroot virtually consist of pure starch. Seeing that they are all imported and that our cereal food and potatoes afford the necessary quantity of starch, we shall do well to dispense with them, although there is no harm in using arrowroot for invalids. Tapioca and sago, as well as rice, are largely employed for milk puddings—in this country far too largely. These puddings use up a lot of milk which should be reserved for butter and cheese, and they belong to the injurious class of pap foods on which our children are fed all too copiously—but more of this later.

Sugar.—In view of the fact that all the sugar consumed in this country is imported and has to be paid for in exports, it is very desirable that it should not now be consumed in unnecessary amount. Widespread misapprehension prevails as to the value of sugar as a food. The fact is that we could get on very well without any sugar at all. Primitive man had none but the limited quantity furnished by wild honey. Nowadays, by the cultivation of the sugar-cane and beetroot, our yearly supply runs into thousands of tons, and it is consumed by the inhabitants of this country in vastly greater quantities than was the case even a few generations back. Because sugar is so cheap and has a high "caloric" value it is supposed to be an economical food for the poor. This, as Dr. Sim Wallace points out, is a fallacy: "Every penny spent on sugar by the poor is from the point of view of nutrition simply wasted, inasmuch as the poor are by force of circumstances compelled to obtain the great bulk of their nourishment from cereals and potatoes, which contain a relative superfluity of saccharide material." And it should be remembered that starch enters the blood in much the same form as cane sugar—i.e., as a monosaccharide. Sweetstuff shops do an infinity of harm, for unless special precautions are taken—and they rarely, if ever, are—sweets are highly injurious to the teeth; we should be better off without them. In many parts of the country where war allowances abound the sale of sweets, as of many other unnecessary articles, has gone up enormously during the war.

All money spent on sweets is worse than wasted. None should be thus spent. The money saved in this way should be loaned to the State, and the tens of thousands of persons engaged in the sweet industry be transferred to occupations more profitable to the country. The surest way of economising in sugar is to put a heavy tax upon it. Our annual import of this article costs us some £22,000,000 sterling. One half of this could quite easily be saved.

It is true that sugar is useful for preserving purposes, but even here its consumption might with advantage be considerably reduced. From the point of view of nutriment jams are of little more value than sugar alone. Not only do they consist of some 75 per cent. of sugar, but most of the virtue of the fresh fruit is lost in the process of boiling. Moreover, while fresh fruit cleanses the mouth and teeth and thus promotes "oral hygiene," jams leave the mouth in an unhygienic state and tend to give rise to decay of the teeth.

Vegetables.—Practically all our vegetables are home-grown, and perhaps for this reason people are apt to be very wasteful with them. Special care should be taken not to waste the highly nutritious potato.

Fruits.—Provided there is an adequate supply of vegetables, fruit, though a useful adjunct to the dietary, could, if the necessity arose, be dispensed with entirely. Imported fruits, such as oranges, apples, bananas, figs, and dates, are not necessary. A question of some difficulty is how to deal with the excess of home-grown fruits (e.g., plums, apricots), which are highly perishable. It is not desirable to make large quantities of jam, for this would use up much sugar which, as we have seen, is not a necessary food. But fruit can be bottled by the use of no more than a dessert-spoonful of sugar to the pound, or even, I understand, without any sugar at all. The fruit is placed in a receptacle. This is filled up with water. It is then sterilised by heat for half an hour, and finally sealed hermetically by means of a screw top.

Tea, coffee, and cocoa.—These are unnecessary, and inasmuch as they are all imported they should be economised to the utmost. Tea and coffee are pure stimulants and have no actual nutritive value. In a time of stress we could do without them quite well. Cocoa, besides being slightly stimulant, is nutritious, but it is an expensive food.

(To be concluded.)

CANADA.

(FROM OUR OWN CORRESPONDENTS.)

Public Health Department needed in Canada.

Dr. Steele, M.P. for North Oxford, Ontario, introduced into the Canadian House of Commons recently a resolution calling for the immediate creation in the Canadian Government of a Department of Public Health. The need for such a department was greater now than it ever had been, and would be still greater as soon as the war is ended, Canadians anticipating an enormous immigration into the Dominion from European countries. At the present time health matters coming under the jurisdiction of the Federal Government are administered from eight or ten different departments of the public service. The object would be to consolidate these under one responsible Minister of the Crown. It is claimed that 40 per cent. of Canada's infant mortality could be saved were there a properly constituted department of health to look after such matters. The Canadian Medical Association appointed a special committee as long ago as 1901 on this very subject, and year after year the matter has been urged upon the Government at Ottawa, but no step has been made forward in the 15 years.

Health and Hygiene in Montreal.

During the year 1915 a series of conferences was held in Montreal under the auspices of the Department of Health in connexion with the campaign against tuberculosis and infant mortality. In all 147 lectures were given and the average attendance was over 200. The Health Department has decided to continue these conferences during 1916. In the month of January another new public bath was opened in the city, making a total of 14 baths now under municipal direction. These are available to women upon certain days of the week.

The Care of the Feeble-Minded.

In January a meeting was held in Toronto to discuss the care of the feeble-minded in Canada, on the basis of the report of the Special Commission of the Ontario Government. The statistics presented proved the great prevalence of feeble-mindedness throughout the Dominion, and the report suggested remedies, including classes for backward children in the public schools, suitable institutions for the education of the worst cases, compilations by the medical officer of health of a register of defectives, a psycho-educational clinic, a farm cottage system, the appointment of a permanent board whose membership might include the Provincial Secretary, the Minister of Education, and the Lieutenant-Governor of the province. The increase of the feeble-minded in Canada is a serious matter, which must continue to claim the attention of the provincial governments.

Military Hygiene in Victoria, B.C.

A regiment of fine men, hunters, lumbermen, and the like, is quartered at Victoria in a drill-hall which, as anyone with any expert knowledge of such things can see, is most unsuitable for a barrack, with its small amount of window area per man. Further, it is dusty and overcrowded. The sick-list is said to be very high, and two men have died of pneumonia after measles. The officers of the regiment, medical and lay, are reported to be in protest unavailingly, and recruiting is being pushed also to replace the men who have died, men who, it is thought, need not have been lost had the request of the commanding officer been granted for leave to put his regiment under canvas. This case requires to be very quickly dealt with by the authorities, for it was under just such conditions that in the "fifties" of last century the British Guards used to lose so many men from phthisis. Nowadays more is known of barrack hygiene, and consumption is kept down by avoiding overcrowding.

March 4th.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENTS.)

Plague and Rat Destruction.

THE plague deaths in India during the week ending Jan. 29th numbered 6620 against 8533 cases. The Bombay Presidency and Sind had 1772 deaths, the Madras Presidency 366 Bihar and Orissa 582, the United Provinces 1239, the Punjab 40, Burma 347, the Central Provinces 778, Mysore State 130, Hyderabad State 1271, Central India 81, and Kashmir 14. The smoking out of rats is being vigorously carried on throughout the Punjab, especially in those villages where plague was recently seen and where plague is again appearing. The work is now done by means of a bellows which blows the fumes from burning bhoosa and sulphur into the rat-holes. The smoke traverses from one house to another, and appears out of the holes in the walls and floors of houses adjacent. The effectiveness of this work is, however, sadly diminished by the customary difficulty of getting the villagers to combine for a common object. Thus, although the rats in the houses properly smoked out are really killed, those in the houses where objections were raised spread again through the village.

The Detection of Milk Adulteration.

A bulletin, No. 57, of the Pusa Research Institute, entitled "The Detection of Added Water in Milk in India," by Dr. J. W. Leather, the Imperial agricultural chemist, states that the usual English method for detection of added water

is practically useless in India. In England the total solids must not be less than 8·5 per cent., while in India a wider lim't is admissible, as there is no means of ascertaining the respective proportion of buffalo and cow's milk when mixed. Thus any fair standard for solids would be too high for cow's milk alone, and a standard even as high as 8·3 per cent. would still leave it open to the buffalo milk vendor to add from 10 to 20 per cent. of water without fear of detection. Dr. Leather describes two other methods for the detection of added water—the refractive index of the milk serum and the freezing-point of the milk. The former would hardly detect 10 per cent. of added water. The latter method he finds much more dependable, and by it the addition of even very small quantities of water are readily detected.

Small-pox Epidemic in Madras.

The existence of small-pox in an epidemic form in Madras is notified, and the health department of the Madras corporation is doing its best to grapple with the disease, which is said to have been introduced by the large influx of visitors during the Christmas holidays. Just now there are a large number of pilgrims from the north passing through Madras on their way to Rameswaram.

Plantain Juice as an Antidote for Snake-bite.

The *Times of Ceylon* reports that at Colombo, in the presence of a large gathering, including doctors, Mr. Donald Obeysekere demonstrated the efficacy of plantain juice as an antidote to snake-bite. Mr. Obeysekere liberated a cobra from a gunny-bag face to face with a valuable bull terrier, upon which the demonstrator's confidence in his remedy led him to experiment. The dog, however, broke the cobra's back after a ten minutes' fight, during which he had succeeded in avoiding its fangs. The bull terrier was then held off, and a village pi-dog was brought in and was severely bitten by the snake. It howled with pain and collapsed in a few minutes. The dog was then given plaintain juice freshly expressed from some young trees of no particular variety, and when about a breakfast-cup had been administered it is stated that the dog began to revive. Within half an hour it was on its feet, and the doctors present were satisfied that it had got over the effects of the poison. The journal adds that the experiment was then repeated with a cock, which was likewise bitten badly and recovered. Dr. Fabian Hirst, who was present, was asked to make further experiments, the result of which will be awaited with interest.

March 5th.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.[1]

IN the 96 English and Welsh towns with populations exceeding 50,000 persons at the last Census, 7859 births and 5722 deaths were registered during the week ended Saturday, March 25th. The annual rate of mortality in these towns, which had been 17·8, 17·2, and 17·9 per 1000 in the three preceding weeks, fell in the week under notice to 16·5 per 1000 of their aggregate population, estimated at 18,136,180 persons at the middle of the year 1914. During the first 12 weeks of the current quarter the mean annual death-rate in these towns averaged 15·6, or 0·4 per 1000 higher than that recorded in London The annual death-rate last week ranged from 4·3 in Enfield, 6·3 in Ilford, 6·6 in Eastbourne, 8·1 in Walthamstow, and 8·8 in Ealing, to 22·9 in Preston, 23·0 in Liverpool, 23·1 in Dewsbury, 25·5 in Tynemouth, 27·0 in Swansea, and 28·5 in Barrow-in-Furness.

The 5722 deaths from all causes were 493 fewer than the number in the previous week, and included 391 which were referred to the principal epidemic diseases, against 345 and 378 in the two preceding weeks. Of these 391 deaths, 137 resulted from whooping-cough, 115 from measles, 65 from infantile diarrhœal diseases, 53 from diphtheria, 12 from scarlet fever, and 9 from enteric fever, but not one from small-pox. The annual death-rate from these diseases was equal to 1·1 per 1000, and equalled that in the previous week. The deaths attributed to whooping-cough, which had been 114, 85, and 93 in the three preceding weeks, rose to 137, and caused the highest annual death-rates of 1·2 in Derby and in Stockport, 1·3 in Gateshead, 1·8 in Cambridge and in Stockton-on-Tees, and 2·1 in Warrington. The deaths referred to measles, which had increased from 62 to 127 in the seven preceding weeks, fell to 115; the highest death-rates from this disease were 2·0 in Grimsby, 2·9 in Newport (Mon.), 3·0 in Swansea, 3·4 in Tynemouth, 3·5 in Stockton-on-Tees, and 7·2 in Rochdale. The fatal cases of diarrhœa and enteritis (among infants under 2 years), which had been 65, 60, and 68 in the three preceding weeks, fell to 65, and included 14 in London, 7 in Birmingham, 5 in Manchester, and 3 in Liverpool. The deaths attributed to diphtheria, which had been 82, 54, and 61 in the three preceding weeks, fell to 53, of which 11 occurred in London, 5 in Birmingham, and 3 in Liverpool. The deaths referred to scarlet fever, which had been 17, 13, and 19 in the three preceding weeks, declined to 12, and included 2 in St. Helens. The 9 fatal cases of enteric fever, of which 2 were registered in Sheffield, were equal to the average in the earlier weeks of the quarter.

The number of scarlet fever patients in the Metropolitan Asylums Hospitals and the London Fever Hospital, which had declined from 2257 to 1839 in the nine preceding weeks, further fell to 1783 on Saturday last; 210 new cases were admitted during the week, against 234, 216, and 193 in the three preceding weeks. These hospitals also contained on Saturday last 1443 cases of diphtheria, 237 of whooping-cough, 120 of measles, and 49 of enteric fever, but not one of small-pox. The 1435 deaths from all causes in London were 166 fewer than in the previous week, and corresponded to an annual rate of 16·6 per 1000. The deaths referred to diseases of the respiratory system, which had been 373, 344, and 405 in the three preceding weeks, fell to 337 in the week under notice, and were 142 below the number registered in the corresponding week of last year.

Of the 5722 deaths from all causes in the 96 towns, 171 resulted from violence and 429 were the subject of coroners' inquests, while 1664 occurred in public institutions. The causes of 42, or 0·7 per cent., of the total deaths were not certified either by a registered medical practitioner or by a coroner after inquest. All the causes of death were duly certified in London and in its 14 suburban districts, in Leeds, Bristol, Bradford, Hull, Newcastle-on-Tyne, and in 58 other smaller towns. Of the 42 uncertified causes, 11 were registered in Birmingham, 6 in Liverpool, 3 each in Manchester, and Tynemouth, and 2 each in St. Helens, Rochdale, Preston, Blackpool, and Darlington.

[1] The Scottish and Irish figures are not forthcoming owing to the delay in the mails.

VITAL STATISTICS OF LONDON DURING FEBRUARY, 1916.

In the accompanying table will be found summarised complete statistics relating to sickness and mortality in the City of London and in each of the metropolitan boroughs. With regard to the notified cases of infectious diseases, it appears that the number of persons reported to be suffering from one or other of the 10 diseases specified in the table was equal to an annual rate of 6·0 per 1000 of the population, estimated at 4,516,612 persons; in the three preceding months the rates had been 7·8, 6·3, and 6·5 per 1000 respectively. The lowest rates in the month were recorded in Kensington, Chelsea, the City of Westminster, St. Marylebone, and Hampstead; and the highest rates in Stoke Newington, Finsbury, Shoreditch, Bethnal Green, and Stepney. The prevalence of scarlet fever showed a further decline from that recorded in other recent months; this disease was proportionally most prevalent during the month in Holborn, Finsbury, Shoreditch, Bethnal Green, and Greenwich. The Metropolitan Asylums Hospitals contained 1956 scarlet fever patients at the end of the month, against 2896, 2431, and 2157 at the end of the three preceding months; the weekly admissions averaged 210, against 329, 248, and 249 in the three preceding months. Diphtheria was slightly more prevalent than it had been in the preceding month; among the several boroughs the greatest proportional prevalence of this disease was recorded in Stoke Newington, Stepney, Battersea, Wandsworth, and Camberwell. The number of diphtheria patients under treatment in the Metropolitan Asylums Hospitals, which had been 1551, 1476, and 1491 at the end of the three preceding months, had risen again to 1538 at the end of the month; the weekly admissions averaged 198, being 195, 177, and 198 in the three preceding months. The prevalence of enteric fever showed a slight increase; this disease was proportionally most prevalent in Paddington, Kensington, the City of Westminster, Poplar, Lambeth, and Wandsworth. There were 50 enteric fever patients under treatment in the Metropolitan Asylums Hospitals at the end of the month, against 57, 50, and 44 at the end of the three preceding months; the weekly admissions averaged 7, which was also the average in each of the three preceding months. Erysipelas was proportionally most prevalent in Paddington, Shoreditch, Bethnal Green, Poplar, and Woolwich. The 19 cases of puerperal fever notified during the month included 3 in Bethnal Green and 2 each in St. Pancras, Islington, and Lambeth. The 30 cases of cerebro-spinal meningitis included 4 in Kensington, 3 in Hackney, 3 in Shoreditch, 3 in Bermondsey, 2 in St. Pancras, and 2 in Finsbury; the 2 cases of poliomyelitis belonged to St. Pancras and Stepney respectively.

ANALYSIS OF SICKNESS AND MORTALITY STATISTICS IN LONDON DURING FEBRUARY, 1916.

(*Specially compiled for* THE LANCET.)

CITIES AND BOROUGHS.	Estimated population in the middle of 1914.	NOTIFIED CASES OF INFECTIOUS DISEASE.											DEATHS FROM PRINCIPAL INFECTIOUS DISEASES.								Deaths from all causes.	Death-rate per 1000 living.†

* Including membranous croup. † The death-rates are corrected for variations in sex and age constitution of the populations of the several boroughs, the population of England and Wales being taken as the standard.

The mortality statistics in the table relate to the deaths of persons actually belonging to the several boroughs, the deaths occurring in institutions having been distributed among the boroughs in which the deceased persons had previously resided; the death-rates from all causes are further corrected for variations in the sex and age constitution of the populations of the several boroughs. During the four weeks ending Feb. 26th the deaths of 5023 London residents were registered, equal to an annual death-rate of 14·5 per 1000; in the three preceding months the rates had been 16·2, 17·3, and 13·5 per 1000 respectively. The death-rates for the month ranged from 10·0 in Hampstead, 11·0 in Lewisham, 12·3 in Wandsworth, 12·5 in Fulham and in Holborn, and 12·6 in Hammersmith, to 16·6 in St. Pancras, 16·7 in Stepney, 16·9 in Deptford, 18·2 in the City of London, and 18·6 in Finsbury. The 5023 deaths from all causes included 303 which were referred to the principal infectious diseases; of these, 30 resulted from measles, 21 from scarlet fever, 62 from diphtheria, 123 from whooping-cough, 3 from enteric fever, and 64 from diarrhœa and enteritis among children under 2 years of age. No death from any of these diseases was recorded in the City of London; among the metropolitan boroughs they caused the lowest death-rates in Fulham, Kensington, Hampstead, and Holborn: and the highest rates in Chelsea, St. Marylebone, Finsbury, Shoreditch, Stepney, and Greenwich. The 30 cases of measles were equal to only one-seventh of the corrected average number in the corresponding period of the five preceding years, and included 5 in Deptford, 4 in Finsbury, 3 in Hammersmith, 3 in Stepney, and 3 in Greenwich. The 21 fatal cases of scarlet fever were 4 in excess of the average number, and included 4 in Islington and 2 each in St. Pancras, Finsbury, Shoreditch, Stepney, Battersea, and Greenwich. The 62 deaths from diphtheria were 12 more than the corrected average number; this disease was proportionally most fatal in Chelsea, Stoke Newington, Finsbury, Bethnal Green, Southwark, Bermondsey, and Wandsworth. The 123 deaths from whooping-cough were 17 above the corrected average, the highest death-rates from this disease being recorded in Chelsea, Shoreditch, Bethnal Green, Stepney, Southwark, Greenwich, and Woolwich. The 3 deaths from enteric fever were 10 below the corrected average number, and belonged to St. Pancras, Islington, and Shoreditch respectively. The mortality from diarrhœa and enteritis among children under 2 years of age was proportionally greatest in Chelsea, St. Marylebone, Shoreditch, Southwark, and Battersea. In conclusion, it may be stated that the aggregate mortality in London in February from the principal infectious diseases, excluding diarrhœa, was 39·1 per cent. below the average.

THE SERVICES.

ROYAL NAVY MEDICAL SERVICE.

Surgeon J. H. Wright, Reserve List of Medical Officers, has been promoted to the rank of Staff Surgeon on the Reserve List of Medical Officers.

ARMY MEDICAL SERVICE.

Temporary Lieutenant-Colonel W. H. Willcox, R.A.M.C., to be temporary Colonel.

ROYAL ARMY MEDICAL CORPS.

Major J. Powell is restored to the establishment.

Major R. Jones, R.A.M.C. (T.F.), to be temporary Lieutenant-Colonel.

To be temporary Majors: G. D. Gray and Captain E. W. H. Groves, R.A.M.C. (T.F.).

Captain A. F. C. Martyn is seconded for service with the Egyptian Army.

E. W. Skinner to be temporary Captain.

The undermentioned temporary Lieutenants relinquish their commissions: O. Barton, N. Keith, J. A. Thoms, W. K. Hall, and E. N. Drier.

To be temporary Lieutenants: D. P. Thomas, A. G. Alexander, W. G. Harnett, A. J. Chillingworth, H. M. Harrison, R. A. Quinn, J. I. Enright, C. E. G. Bateman, J. G. T. Thomas, B. S. Simmonds, D. S. Graham, A. A. E. Newth, J. R. Wylie, H. W. Harding, J. Young, G. C. B. Hawes, A. E. Foerster, C. W. Morrison, W. J. Porteous, J. S. Annandale, A. J. D. Rowan, A. Morgan, W. G. Weston

J. St. J. Dundon, C. R. Howard, J. T. H. Madill, N. J. Judah, J. B. Yelf, J. F. Mackenzie, J. E. Manlove, C. O'Malley, S. C. W. Iredale, G. B. Mason, C. Townshend, C. L. Forde, P. A. McCallum, T. R. Davey, C. Costello, A. A. B. Scott, W. Scot, W. H. Soady, E. Nuttall, J. K. Bell, J. Cathcart, J. J. Dowdall, W. H. Thomas, W. J. Murphy, J. C. Anderson, R. C. Corbett, W. G. Thomas, E. B. Morley, J. F. Nicholson, R. B. Gorst, D. A. Crow, G. L. Lawlor, J. B. Fairclough, S. A. McClintock, A. H. Arnott, P. C. Conran, A. C. Lambert, R. E. McLaren, I. O'Keeffe, E. C. Lindsey, and R. V. Murphy.

Temporary Honorary Lieutenants to be temporary Lieutenants: S. R. Prall and W. Thomas.

Canadian Army Medical Corps: N. C. Wallace to be temporary Honorary Major. F. J. Ewing to be temporary Captain.

SPECIAL RESERVE OF OFFICERS.

Royal Army Medical Corps.

Lieutenants (on probation) C. A. Slaughter and W. L. A. Harrison are confirmed in their rank.

TERRITORIAL FORCE.

Royal Army Medical Corps.

Highland Mounted Brigade Field Ambulance: Captain A. Mowat to be temporary Major whilst in command of a Field Ambulance.

Yorkshire Mounted Brigade Field Ambulance: Captain A. H. Benson to be temporary Major whilst in command of a Field Ambulance.

East Lancashire Field Ambulance: Major W. L. Bentley to be temporary Lieutenant-Colonel whilst in command of a Field Ambulance.

Lowland Field Ambulance: Major M. Dunning to be temporary Lieutenant-Colonel whilst in command of a Field Ambulance.

South Midland Field Ambulance: Lieutenants to be Captains: H. N. Crowe, W. J. F. Craig, and J. Bannerman.

Northumbrian Field Ambulance: Lieutenant P. J. Sheedy to be Captain.

Wessex Field Ambulance: Lieutenant E. H. Helby to be Captain.

Eastern General Hospital: Lieutenant O. Inchley to be Captain.

London General Hospital: Major J. Calvert to be Lieutenant-Colonel. Captain F. W. Andrewes to be Major. Major (temporary Colonel, A.M.S.) A. H. Tubby to be Lieutenant-Colonel, and remain seconded. The undermentioned Captains to be Majors:—F. F. Burghard, and remain seconded, A. M. Gossage, and H. F. Waterhouse.

Northern General Hospital: Lieutenant H. W. Kerrigan to be Captain.

Western General Hospital: Lieutenants F. H. Lacey and J. T. Williams to be Captains.

London Sanitary Company: C. N. Atlee to be Lieutenant.

North Midland Divisional Sanitary Section: Lieutenant A. White to be Captain.

East Anglian Field Ambulance: Captain L. H. Hutchins relinquishes his commission on account of ill-health. Lieutenant (temporary Captain) G. C. Gray to be Captain.

London (City of London) General Hospital: Lieutenant R. J. W. A. Cushing to be Captain.

Wessex Casualty Clearing Station: Lieutenant T. J. Wright to be Captain.

West Lancashire Divisional Sanitary Section: Lieutenant A. Reid, from London Sanitary Company, to be Lieutenant.

London (City of London) Field Ambulance: Lieutenant A. H. Platt to be Captain.

Southern General Hospital: To be Captains: Lieutenants K. H. Gill and G. L. Wilkinson.

London (City of London) Sanitary Company: Lieutenants to be Captains: M. Greenwood, P. Hartley, and E. R. Matthews.

Eastern Mounted Brigade Field Ambulance: To be Lieutenants: E. H. Coyne and P. J. Smyth.

Welsh Border Mounted Brigade Field Ambulance: Lieutenant W. Morgan resigns his commission.

Highland Field Ambulance: G. Torrance to be Lieutenant.

Home Counties Field Ambulance: C. C. Robinson to be Lieutenant.

London Sanitary Company: A. E. Jury to be Lieutenant.

South Midland Casualty Clearing Station: To be Lieutenants: A. G. Banks and C. A. Raison.

Attached to Units other than Medical Units.—To be Majors: Major W. M. Hamilton, from the Territorial Force Reserve, and Captain D. E. Dickson. To be Captain: Lieutenant L. S. Willcox. To be Lieutenants: H. Jacques and P. A. Chillcott. Major G. S. Mill relinquishes his commission on account of ill-health.

The Arnott gold medal for conspicuous gallantry at the front was presented to Captain W. Loughman, R.A.M.C., on St. Patrick's Day by the Irish Medical Schools' and Graduates' Association.

Correspondence.

"Audi alteram partem."

THE DANGER TO CIVILIAN COMMUNITIES OF A TYPHOID-PARATYPHOID OUTBREAK.

To the Editor of THE LANCET.

SIR,—As one who has taken a special interest in enteric fever for many years and has had opportunities of looking at this disease from a varied point of view, I was naturally very interested in your annotation on this subject in THE LANCET of Feb. 12th and also in the letter in the following issue by Dr. R. Donaldson, whom I had the pleasure of meeting a short time ago when I was attracted to Reading by the news that there had been an unusual amount of enteric fever in that town.

I may say at once that, in my opinion, the danger of an outbreak of the enteric group of diseases caused by the return of soldiers from the front is very small indeed. The carrier is, of course, the indirect cause of all outbreaks, either through water, milk, flies, or direct contact, but provided reasonable precautions are taken with milk and water the risk from direct contact is insignificant. Let me give briefly a few of the reasons for this belief. We start with the fact that experience in India and at home has shown that about 2 per cent. of cases of enteric fever become chronic carriers. Every town in England must contain a large number, the total having been estimated by some to be as much as 4 per 1000 of the population, yet the enteric-rate in English towns is steadily declining, while the actual number of cases attributed to this cause works out at about 1 in 10,000 per year, although overcrowding and squalor are not unknown among the poorer classes. In December, 1904, an epidemic of 1000 cases broke out in Lincoln, but during the time that the temporary and chronic carriers were returning to their homes in increasing numbers the number of cases was steadily decreasing, until in August there were none at all, and since 1904 the enteric-rate of Lincoln has continued to diminish.

Again, if direct contact is a dangerous source of infection the disease ought to be common in troopships. For the last 25 years an average of about 50,000 troops have travelled in this way, and numerous carriers must have been present among the invalids and men returning from India, Egypt, and South Africa; yet, according to army medical reports, cases contracted on board ship are very rare indeed. After the South African War the number of carriers must have been considerably increased in England, but the disease has steadily diminished.

To come to Reading, where the outbreak is attributed to the soldiers, if it were due to the cases in the War Hospital one would expect it to focus round that area, but it is not so. If it is due to soldiers in billets, Reading so far is the only town that reports an excess of the disease, though we may assume that the conditions are the same as in most towns and even villages in England. Dr. Donaldson thinks that because out of 40 cases one was paratyphoid A a military source of the disease is probable. As it is only within the last few years that any notice has been taken of paratyphoid fevers, the actual number of such cases occurring in England is rather an unknown quantity. In India, where blood culture has been practised for several years, experience shows that the bacilli found in blood of patients treated in enteric wards are very varied in character.

These considerations naturally make one ask if the water-supply as a cause can be absolutely excluded. Dr. Donaldson admits that "the only obvious thing in common to all the cases is the water-supply, which, being river water, might conceivably be incriminated"; he does not state, though I have been so informed, that B. coli were present in 1 c.c. of water. The medical officer who went to Reading to report on behalf of the military authorities permits me to say that he certainly thought the outbreak was due to water in some way or other.

I have long been of opinion that the danger of infection by direct contact from carriers has been very much exaggerated. We invalid carriers out of the army into civilian life, but apparently nothing happens. The Local Government

Board Reports show numerous cases of infection by direct contact, but they occur among a population of millions, and include milk epidemics. It is generally agreed in India that, although milk and water epidemics have occurred, enteric in the past was chiefly due to some other cause. This could hardly have been direct contact from carriers, as it can be shown easily that the disease was one of stations and seasons and had no relation to the probable number of carriers among the troops, and the sudden decline of the disease started before the practice of isolating carriers commenced. To my mind the strongest argument against the case for carriers is the fact that even with soap and water it is difficult to disinfect the hands if soiled with infected fæces. We know in India that natives get enteric fever, so there must be carriers among them. The ordinary native servant, a vegetable feeder, has his bowels open twice a day, and completes his toilet by directly handling fæcal matter. Next he cleans his hands with water, possibly with mould, and then probably proceeds to prepare bread and butter, or handle tea-cloths or clean plates for his master's table. Under such conditions the amount of enteric fever should be enormous, yet Bombay and Calcutta, both cities with a large European population, have been singularly free from it for the last 30 years.

The question of carriers is very important. At the present time we are keeping a large number of beds in hospitals occupied by convalescents, and sometimes by perfectly healthy men, because we are afraid to let them out into barracks. Does the danger warrant our taking all this trouble and incurring all this expense and keeping fighting men from the front? My answer is: Let the urine only of typhoid convalescents be examined; take every precaution with the rare and dangerous urinary carrier, but ignore altogether the fæcal carrier.

I am, Sir, yours faithfully,

N. FAICHNIE,

Tidworth, Hants, March 23rd, 1916. Lieutenant-Colonel, R.A.M.C.

THE SHORTAGE OF DRUGS.

To the Editor of THE LANCET.

SIR,—Even in military hospitals one is constantly hampered by the shortage of indispensable drugs. The poorer part of the population must suffer far more. The shortage of the salicylate group is most grievous, and I write to suggest the importance of growing the common willow, *Salix alba*, as well as wintergreen, *Gaultheria procumbens*, and birch, *Betula lenta*. Wintergreen and willow will grow on any damp soil without cultivation. Thousands of acres of such soil are wasting in Britain and Ireland, and although the war may be over before we can utilise their medicinal products, there is always use and demand for oil of wintergreen and salicin.—I am, Sir, yours faithfully,

March 24th, 1916. J. C. MCWALTER, M.A., M.D., M.R.I.A.

"ALBUMINURIC NEURO-RETINITIS."

To the Editor of THE LANCET.

SIR,—Dr. Samuel West, in his letter in your issue of March 25th, differentiates albuminuric retinitis into two forms, the exudative and the degenerative, and contends that they are distinct, that the distinction is fundamental, and that they stand in a different relation to two forms of chronic nephritis. These conclusions, he tells us, are the result of long clinical experience, presumably at a general hospital. Possibly ophthalmic cases seen at a general hospital differ in some mysterious way from those met with at a special hospital.

Eighteen years' clinical and pathological experience at ophthalmic hospitals, so far from affording material confirmatory of his views, directly contravenes them. Dr. West's types, if such they may be called, are found also in acute nephritis and in the nephritis of pregnancy. The latter, it is to be observed, has as its most prominent feature a fatty degeneration of the tubal epithelium, and is not really an acute inflammation. So far from any particular appearance of the retina being pathognomonic of a particular variety of kidney disease, no absolute reliance can be placed upon retinal appearances as a distinctive character. In diabetes, for instance, a condition exactly resembling the "typical" albuminuric variety of retinitis is so often found that the examination of the urine alone will reveal the causal agency. This fact is a well-known pitfall for the unwary at ophthalmic hospitals. Many cases of this disease are characterised by the presence of small brilliantly white spots situated in the retina and occupying chiefly the region of the macula; but according to Dr. West these spots are found only in cases of granular kidney. The same is true of leucocythæmia, pernicious anæmia, and arterio-sclerosis and cerebral tumour. The late Sir William Gowers instances a case of intense neuro-retinitis in a chlorotic girl in which, after the subsidence of the swelling, the picture might very well be taken as an example of the "degenerative" type, which, if we take Dr. West as our guide, is pathognomonic of granular kidney. Since albuminuric neuro-retinitis is essentially a degenerative process, nothing is gained by labelling it "degenerative"; to do so is pleonastic.

Both of the types which Dr. West regards as distinctive and of fundamental importance from the diagnostic standpoint are due to the same cause, passive œdema and vascular degeneration. Neither type can be said to be either distinctive or pathognomonic.

I am, Sir, yours faithfully,

Bayswater, W., March 27th, 1916. EDGAR CHATTERTON.

TREATMENT OF SEPTIC WOUNDS WITH GLYCERINE AND ICHTHYOL.

To the Editor of THE LANCET.

SIR,—At a Divisional Rest Station in France, where practically all the operations were of the type carried out in the surgical out-patient department of a civil hospital—namely, the opening of superficial abscesses—it was decided after reading Major Duggan's articles in the *Journal of the Royal Army Medical Corps* to try dressing these cases with glycerine and ichthyol instead of boric fomentations. At first a 20 per cent. but later a 10 per cent. solution spread on ordinary white lint was used, and then for economy commercial instead of pure glycerine was employed. Fifty-nine cases were thus treated after operating under an anæsthetic, besides many others of which no record was kept and in which no anæsthetic was necessary. They included carbuncles, whitlows of all types, and three cases of cellulitis, two of the upper and one of the lower limb.

In favour of this treatment are:—1. Saving of labour and material—one application daily in place of three boric fomentations. 2. Efficiency as a dressing. Several of the cases had been previously treated with boric foments; in these the discharge was never more in 24 hours on the one glycerine and ichthyol dressing than on any one of the fomentations, though these had been changed twice and thrice daily. 3. The dressing does not adhere to the wound. 4. Men voluntarily told the nursing orderlies that they found the ichthyol dressing more soothing. This treatment is therefore recommended to medical officers, civil and military, for use in dressing superficial septic sores and wounds, as being equally efficacious as the boric fomentation, and more economical as regards time and material.

I am, Sir, yours faithfully,

G. G. ALDERSON, M.B., B.C. Cantab., F.R.C.S. Eng.,
Captain, R.A.M.C.

MEDICAL PRACTITIONERS AND AFTER-WAR PROBLEMS.

To the Editor of THE LANCET.

SIR,—The time at which a large number of practitioners who have left their practices and are now serving their country in various parts of the United Kingdom and abroad will be able to return to civil life is, of course, as yet quite uncertain, but it is obvious that a certain amount of anxiety is being felt, and it may not be considered premature to call attention to this matter through your columns.

After the South African War many societies were formed, having for their object the closer association of medical men who had seen service in that campaign. The problems involved in the present war are infinitely more exacting and vital.

The suggestion is put forward that instead of waiting till after the war, an association might be at once formed of practitioners interested. A central organising committee consisting of those serving in, or near, London would be necessary, and the support likely to be accorded the movement from those serving in distant stations could be easily estimated.—I am, Sir, yours faithfully,

March 24th, 1916. TWENTY MONTHS' SERVICE.

The War.

THE CASUALTY LIST.

THE following names of medical officers appear among the casualties announced since our last issue:—

Died.

Captain R. F. Hebbert, I.M.S., was a student of St. Thomas's Hospital, London, and joined the Indian Medical Service when he qualified in 1906.

Colonel J. Harper, R.A.M.C. (T.F.), Assistant Director of Medical Services, 1st London Division (T.F.), qualified in 1881, and was in practice in London.

Wounded.

Lieutenant-Colonel E. A. Wraith, R.A.M.C., 1st North Midland Field Ambulance (T.F.).

Captain G. D. Ferguson, R.A.M.C., attached to the Royal Field Artillery.

Captain R. Condy, R.A.M.C.

Lieutenant J. P. Musson, R.A.M.C., attached to the 2nd Suffolk Regiment.

Lieutenant J. Young, R.A.M.C.

DEATHS AMONG THE SONS OF MEDICAL MEN.

The following sons of medical men must be added to our lists of those who have fallen during the war:—

Captain J. A. Graham, 7th Lincoln Regiment, youngest son of the late Brigade-Surgeon H. W. Graham, Bengal Army.

Lieutenant M. E. King, 13th Battalion Middlesex Regiment, third son of the late Dr. H. W. King, of Chester, Brigade-Surgeon-Lieutenant-Colonel of the Cheshire Volunteer Infantry Brigade.

Second Lieutenant G. K. Smith, 5th Middlesex Regiment, younger son of Dr. H. Smith, of Chatham.

Second Lieutenant C. W. Kenyon, Royal Sussex Regiment, attached to a Trench Mortar Battery, son of Dr. G. H. Kenyon, of Horsham, Sussex.

THE CENTRAL MEDICAL WAR COMMITTEE: CONFERENCES OF REPRESENTATIVES OF LOCAL MEDICAL WAR COMMITTEES.

We published last week an account of the conferences which have been held at Leeds and London between representatives of the Local Medical War Committees of the districts. The following notes deal with the conferences at Birmingham and Bristol.

The conference of representatives of the Local Medical War Committees in the Midlands and North Wales was held in the Midland Medical Institute, Birmingham, on March 23rd. The chair was taken by Dr. W. J. Garbutt, chairman of the Birmingham Local Medical War Committee, and the arrangements were made by Mr. J. J. Bekenn, honorary secretary of the same committee. There were about 100 present, including a number of Birmingham medical men of military age. Major Lucas, Mr. N. Bishop Harman, and Dr. Alfred Cox attended on behalf of the Central Medical War Committee. After a statement had been made on the general situation, questions were invited and answered. The questions were very similar to those raised at the Leeds and London meetings as reported in THE LANCET of March 25th. The representatives of the North Staffordshire Committee were anxious that the Central Medical War Committee should issue some general plan for dealing with the practices of men who had died on service. The example of Nottingham, which formulated such a scheme in September last, was mentioned, and the representatives of the Central Committee undertook that some model arrangement should be issued to Local Committees. A suggestion was made that the Central Committee would be improved if it contained representatives of provincial industrial practice. In reply it was pointed out that the Committee had no power to coöpt more members, and that any change in its composition must be dealt with at the next Representative Meeting. The representative of Mid-Staffordshire moved a resolution from that committee urging that if enrolment were necessary the Government should make it compulsory. Other representatives declared that they had no mandate to vote on such a proposition, and the chairman ruled it out of order. Votes of thanks to the representatives of the Central Committee and the chairman closed a very successful meeting.

The conference of representatives of the Local Medical War Committees in the South-Western and Western Counties and in Central and South Wales was held in the University at Bristol on March 24th. The chair was taken by Mr. G. T. Myles, chairman of the Bristol Local Medical War Committee, and Mr. H. F. Devis, honorary secretary of that committee, was responsible for the arrangements. There were over 30 representatives present. Mr. T. Jenner Verrall, LL.D., chairman, and Dr. Alfred Cox, one of the secretaries of the Central Medical War Committee, attended on behalf of that Committee. Mr. Verrall and Dr. Cox dealt with the reasons for the adoption of the enrolment scheme and many of the general difficulties connected with it. Questions were then invited. Strong exception was taken from more than one area to the presence in Territorial hospitals of men of military age who had not undertaken the Imperial obligation. Mr. Verrall pointed out that the Central Committee had been definitely and officially informed that all medical men of military age holding Territorial commissions would be asked either to sign the obligation or resign. He undertook that inquiries would be made as to the cases raised at the meeting. The Swansea representatives stated that the action of certain medical men who had attested and had been exempted or granted postponement by the local tribunal had had a very bad effect on the work of their committee, so much so that they had resolved not to press for enrolment. They declared that the military representative at the tribunal had taken no action to prevent medical men from being exempted—rather the reverse. Representatives from Glamorgan and from Somersetshire stated that the action of the Local Insurance Committees in placing unnecessary difficulties in the way of men who desired to offer for military service made it doubtful whether any more men could be got from those areas. Mr. Verrall asked that such cases should be reported fully to the Central Committee, which would undertake to place them before the Commissioners, who up to now had shown every disposition to facilitate panel practitioners going on military service. The North Glamorgan representative said he saw no better plan for satisfying the medical needs of the army than the enrolment scheme which, if a success, would redound to the credit of the profession. He urged those present to put all their energies into it. Votes of thanks were passed to Mr. Verrall, Dr. Cox, and the chairman of the meeting.

JOINT COMMITTEE OF THE ENGLISH ROYAL COLLEGES TO ADVISE ON MEDICAL RECRUITING.—Last week we noted the recent resolution of the Royal College of Physicians of London expressing its willingness to join the Royal College of Surgeons of England in forming an Advisory Committee to give advice to the Government in relation to medical men in the metropolitan district required for service in the army, and to assist in cases of special difficulty arising elsewhere in England and Wales, and coming before the Central Tribunal of the Military Service Act. This Advisory Committee has now been appointed, the names being: from the College of Physicians, Dr. Frederick Taylor (President), Dr. J. Galloway, Dr. Sidney Martin, and Dr. W. Pasteur; from the College of Surgeons: Sir W. Watson Cheyne (President), for whom when absent Sir Rickman J. Godlee will act, Mr. William F. Haslam, Mr. D'Arcy Power, and Mr. Charles Ryall. The joint committee has already commenced its sittings at the College of Physicians and Mr. F. G. Hallett is acting as secretary. It was understood from the outset that the opinion of the Advisory Committee should be transmitted to the Government Department concerned through the Central Medical War Committee without alteration. The College of Surgeons made the further suggestion that time would be saved by the institution of a preliminary survey of the minimum necessities of the several metropolitan hospitals and medical schools in respect of staff. The appointment of this Advisory Committee by the English Colleges should go a long way to set the minds of those at rest who desired a consideration of their personal difficulties from the general standpoint of medical practice and ethics.

WOUNDED ALLIES RELIEF COMMITTEE.—At the English Military Hospital at Limoges, maintained by the Wounded Allies Relief Committee, five French soldiers were recently presented with the Croix de Guerre.

THE King of Serbia has conferred the Third Class of the Order of St. Sava upon Lieutenant-Colonel H. E. M. Douglas, V.C., C.M.G., D.S.O., R.A.M.C., Deputy Assistant Director of Medical Services.

OBITUARY OF THE WAR.

ARTHUR RYLAND CHAVASSE, B.A., M.B. OXON., M.R.C.S.,

CAPTAIN, ROYAL ARMY MEDICAL CORPS.

Captain A. R. Chavasse, who died in France at No. 2 General Hospital, B.E.F., on March 12th, as a result of broncho-pneumonia, was aged 27 years, and was the only son of Lady Chavasse and the late Sir Thomas Chavasse, of Birmingham. He was educated at Harrow School and Hertford College, Oxford, and entered St. Thomas's Hospital, where, after graduating as B.A. and M.B. at Oxford, he held the house appointments of physician, obstetric physician, and casualty officer. He was also resident medical officer to Queen Charlotte's Hospital. He surrendered this appointment in 1914 to join the Red Cross Society in France, then entering the Royal Army Medical Corps as a temporary lieutenant, and working first at Netley and then at No. 4 and No. 2 General Hospitals in France. A fellow officer writes of him that he was devoted to his work and loved by all who came in contact with him. He had recently been promoted captain, when he was taken by the illness which proved fatal.

A life-long friend writes: "Arthur Chavasse was one of those men whom to know was to love. He was a wonderful personality, so full of energy and enthusiasm. He was a devout Churchman and spent his leisure hours, when at St. Thomas's Hospital, in the slums of the East-End. He had an absolute horror of ostentation or publicity. Now we know a little of his endless acts of kindness and of his true generosity." Lady Chavasse has received a message of regret and sympathy from the King and Queen.

DOUGLAS ARTHUR CAMPBELL LAYMAN,

LIEUTENANT, 17TH LANCASHIRE FUSILIERS.

Second Lieutenant D. A. C. Layman, who was killed in France on Feb. 22nd, at the age of 22, was a medical student and the grandson of a medical man. He was educated at Dulwich College, where he was a member of the Officers Training Corps, entering St. Thomas's Hospital in 1913, and taking part of the Second M.B. in July, 1914. The secretary of the hospital writes: "From the first declaration of war Layman was anxious to do his best to help. He made a special appeal for experience in dressing in the Casualty Department, and in October, 1914, went to help with Red Cross work in France. He subsequently did nine months excellent work on the I.M.S. Hospital Ship, *Glengorm Castle*. Even this work did not content him, he wanted to do more, and by obtaining a commission in the Lancashire Fusiliers in September, 1915, and going to the front, he sacrificed everything to his ideal of duty."

THE RED CROSS HOSPITAL UNIT IN MONTENEGRO.—In a recent summary of work issued by the British Red Cross Society and the Order of the Hospital of St. John of Jerusalem in England there is an interesting report, signed by Dr. F. G. Clemow, C.M.G., head of the unit, on the work of the Red Cross Hospital in Montenegro. The unit left England on Jan. 19th, 1915, with three medical men—Dr. Clemow, head of the mission, and Dr. F. W. E. Burnham and Dr. L. V. Tebbs, who subsequently had charge of the general section and infectious wards respectively. The other members of the staff were two nurses, two V.A.D. attendants, and four orderlies. The equipment consisted of material for a hospital of from 70 to 100 beds, the stores being contained in some 400 cases and bales. After considerable delay, owing to weather and war conditions, the unit arrived at Plevlje in March, and took over charge of the hospital there—the principal military hospital in Montenegro. The hospital consisted of two separate sections, one of eight pavilions built by the Austrians, as barracks, during their military occupation, and a hospital building. The first-named buildings were reserved for general and medical cases, and the second for infectious cases. At the time of occupation there were 126 patients in the wards, but the number rapidly doubled, and later rose to more than 300. For a short period Dr. Peyer, a Swiss doctor, and Dr. Vullanovitch and Dr. Krasky, both of the Montenegro service, rendered assistance. Owing to bad sanitation and administration the buildings when taken over were far from ideal for hospital purposes. To increase the accommodation other buildings were taken over, and a vote of £1000 from the British Red Cross Society resulted in the construction of satisfactory hospital buildings. There were a few cases of typhus fever in the wards when the hospital was taken over, and these rapidly increased in number, while to add to the difficulties of the staff first Dr. Tebbs and afterwards Dr. Peyer contracted the disease, and one of the orderlies fell ill and died. At the end of March Dr. Clemow, at the instance of General Vukotitch, drew up a series of army orders for the better preservation of the health of the Serbian troops, and in June took part in a conference at Cettinje on the medical needs of the hospital, the army, and the country generally. The King of Serbia, who subsequently conferred decorations and medals on various members of the unit, received Dr. Clemow and expressed appreciation of the work of the unit. In July, on the expiry of the original six months' contract, Dr. Tebbs and other members of the unit returned home, Dr. W. E. Haigh replacing Dr. Tebbs, and others taking the place of the original staff which maintained its complement of 11 members. Until the month of September the majority of cases admitted to the hospital were of the ordinary medical and surgical character. The measures taken to meet the typhus epidemic of the spring, which steadily subsided, included the establishment of baths and of two disinfecting stations, one in the general and the other in the infectious section of the hospital. Every patient admitted had his clothes removed, was bathed and put to bed, and the clothes thoroughly disinfected either with sulphur or (later on) with formaldehyde. In all 143 cases of typhus were admitted, of which 7 died and 136 recovered. In the surgical wards over 500 major operations were performed and Dr. Burnham gained a well-deserved reputation as a surgeon. At the end of September and beginning of October, in order to provide for the large number of wounded, the result of the combined Bulgarian and Austro-German attack, many cases of chronic or incurable illness were sent to their homes. A casino and concert hall were converted into a hospital which was soon filled, while many of the severely wounded had to be placed in the "infectious" section and of the lightly wounded in the "convalescent hospital." The total numbers rose to well over 300, and at this time, as well as during the typhus epidemic in the spring, the stress of work on all members of the unit was very considerable. In all between 300 and 400 wounded were in the hospital at the final evacuation. The total number of in-patients treated in the hospital was approximately 3000 and that of the out-patients the same. About the middle of November, owing to the pressure of the Austrians, it was found necessary to remove the hospital from Plevlje to Shahovitza. At this time there were 332 patients in the wards, of whom 223 were wounded. In three days 280 patients were sent either to Shahovitza or to their homes, and

when the unit left, which was on Nov. 21st, only 50 patients remained behind. These were left in charge of Dr. Stais, a Greek doctor, and Dr. Kievenaar, a Dutch medical man, who followed the unit next day with the patients. The patients' journey and the adventures of the unit are briefly described by Dr. Clemow, and but little imagination is required to realise the hardships which the party had to endure or to picture their lucky escapes from disaster. In December all the stores were exhausted and the party left Serbia and arrived in England in January, 1916. In closing his report Dr. Clemow bears testimony to the excellent work of all the members of the unit, the best witness to the valuable work of Dr. Tebbs being the low typhus mortality, while equally valuable work was done by Dr. Haigh, and his untiring assistance to all during the retreat deserves, says Dr. Clemow, more than a passing word. Dr. Burnham's work in the surgical wards has already been alluded to.

HEALTH OF MUNITION WORKERS.—The munition workers of this country are fortunate in possessing a health committee which is both alert and enlightened. We have already noticed memorandums dealing with Sunday labour, canteens, the hours of work, and the employment of women. Four others have just appeared in which are considered industrial fatigue and its causes (No. 7). special industrial disease (No. 8), ventilation and lighting of munition factories and workshops (No. 9). sickness and injury (No. 10). All of these are printed at H.M. Stationery Office and may be obtained from Wyman and Sons at the cost of 1*d*. or 1½*d*. To the medical bearing of these pamphlets we shall return later.

PROPHYLAXIS OF VENEREAL DISEASE.—In recent years attempts have been made in all armies and navies to prevent venereal disease by methods of what may be called subsequent prophylaxis. Men after exposure to infection are invited, and indeed constrained, to attend for special washings and anointings which shall prevent the development of any virus they may have picked up. And very often it has been said, by medical officers of small units usually, that the results of these methods have been quite successful. But now, in the *Military Surgeon* (Washington, D.C.) for January, Surgeon (that is, Fleet-Surgeon) R. C. Holcomb, U.S.N, examines the medical statistics of the United States Navy during the six years that have elapsed since, in January, 1909, prophylaxis was commenced, and concludes that "there has since been no drop in the admission-rate, and that therefore the preventive has not prevented." He then asks why the propaganda has failed, and ascribes it to the subsequent prophylaxis being in most cases too long delayed. He himself found, on critically examining records of some 3000 cases, that of those who took precaution within eight hours of exposure only 1·5 developed disease. If precautions were taken between the eighth and the twelfth hour 3·3 per cent. were attacked, but of those who delayed treatment to the second 12 hours 5 per cent. suffered. The experience of the Italian navy is very similar. Venereal prophylaxis, with calomel ointment and protargol, was instituted in October, 1913. and Captain Dr. Serra, a surgeon in that navy, details in the *Annali di Medicina Navale* for October, the benefits this prophylaxis has brought to the group of 2600 men who are under his care at Spezia He concludes that the men who on their return from leave use the prophylactics supplied invariably escape syphilis. The annual report of the Surgeon-General of the United States Navy for 1915 also takes much the same view, ascribing failure to delay, this delay resulting from ignorance, intoxication, or indifference. Surgeon Holcomb thinks the best prophylaxis will be found to be moral and to lie in a better public opinion, a higher self-control.

CHARING CROSS HOSPITAL.—The annual court was held on March 23rd, Mr. George Verity, J.P., presiding, when a very satisfactory condition of affairs was reported. The chairman stated that the hospital was now working at its full capacity of 300 beds, and he was able to report a great improvement in equipment. The hospital mortgage, which 15 years ago was £85,000, had been reduced to £59.000, and any legacies or exceptional amounts received by the hospital were applied towards the liquidation of this capital debt. The officials of the King's Hospital Fund stated that the cost per bed at this hospital was the lowest but one of any in the Metropolitan area. Dr. G. Dickinson's 17 months' gratuitous service as resident medical officer in order to meet the shortage due to the war demands was specially mentioned.

Obituary.

MARY CHARLOTTE MURDOCH, L.R.C.P., L.R.C.S.EDIN., L.F.P.S. GLASG.,

SENIOR PHYSICIAN TO THE VICTORIA HOSPITAL FOR CHILDREN, HULL.

THE death occurred on March 20th of Miss Mary Charlotte Murdoch, senior physician to the Victoria Hospital for Sick Children, Hull.

Mary Charlotte Murdoch was born in Elgin and spent part of her child life and educational period in Lausanne, as well as in London. When the death of her parents left her independent she decided to devote the small sum of money at her disposal to studying for the medical profession, although this resolve meant much self-denial, and in her case considerable courage, as she had to contend already with the gastric hæmorrhages which throughout her life occasionally prostrated her. After obtaining qualifications from the Scottish Corporations, she worked for a time as clinical assistant at the New Hospital for Women in the Euston-road, and was later curator of the museum of the London School of Medicine for Women. In 1892 she became house surgeon to the Victoria Hospital for Children at Hull, a post which she held for two years, when an attack of gastric hæmorrhage compelled her to resign. Upon recovery she was appointed assistant medical officer for the Tottenham Fever Hospital, London, under Dr. R. A. Birdwood, to whose instruction and clinical example she attributed the skill which she undoubtedly possessed in the diagnosis and treatment of acute infectious diseases. In 1894 she returned to Hull, where she had made many friends, and, starting in private practice, met with immediate success. She was appointed honorary assistant physician to the Victoria Hospital, where she had formerly been resident, and three years later became full physician, holding the post at the time of her death. Among other appointments she was physician to the Lees' Walk Home for Girls and to the Hull Central Crêche, and was a certifying surgeon under the Factory Acts. She was also consulting physician to the Harrow Road Hospital for Children in London, and was keenly interested in the suffrage question.

Mary Charlotte Murdoch was more than a successful physician: she was an influential personality. She did much valuable public work when physically not equal to the strain, she was a woman of large sympathies, and invariably acted up to her high ideals, and there is no doubt that in her the medical profession and women workers have lost an outstanding force for good.

GEORGE ALFRED HEBERDEN, M.R.C.S., L.R.C.P., D.S.O.

THE death is announced from Sea Point, South Africa, of George Alfred Heberden, which occurred from heart trouble in January last, in his fifty-sixth year. He had been an invalid for some time, and recently left his home at Victoria West, South Africa, for the Cape, where he somewhat improved. At the beginning of the year, however, he had a relapse, which soon proved fatal. George Heberden bore a name well known in medicine, his great-grandfather being the famous William Heberden, of Heberden's asthma and Heberden's nodes. His grandfather was also a medical man, while his father was a Berkshire clergyman. George Heberden was educated at Jesus College, Cambridge, and later, determining on the medical profession, he entered as a student at St. George's Hospital. He took the Conjoint English qualification in 1888, and almost immediately went to South Africa and entered upon practice at Kenhardt. Afterwards he became district surgeon to Barkly West, where he was when the South African War broke out. His services as medical officer at the siege of Kimberley were of marked value, and for them he received the D.S.O. Subsequently in 1906 he became district surgeon and railway medical officer at Victoria West, which offices he held at the date of his death.

PROFESSOR EUGENI PAVLOV.—A Russian correspondent writing to us from Moscow informs us that the news of the death of Professor Ivan Petrovitch Pavlov, director of the Physiological Section of the Institute for Experimental Medicine at Petrograd, was sent in error. The Professor Pavlov who died in February last was not the famous physiologist, but Professor Eugeni Vasilievich Pavlov, once a prominent Russian surgeon and well known in his own country for his excellent social work. Professor Eugeni Pavlov was 71 years of age.

Medical News.

SOCIETY OF APOTHECARIES OF LONDON.—At examinations held recently the following candidates were successful:—

Surgery.—M. Dwyer (Sections I. and II.), Leeds; J. Fox-Russell (Sections I. and II.), Middlesex Hospital; H. M. Gray (Sections I. and II.), Guy's Hospital; and R. Milne (Sections I. and II.), London Hospital.

Medicine.—M. Dwyer (Section I.), Leeds; E. N. Glover, (Sections I. and II.), Guy's Hospital; and R. Milne (Sections I. and II.), London Hospital.

Forensic Medicine.—C. G. Bunn, Charing Cross Hospital; M. Dwyer, Leeds; E. N. Glover, Guy's Hospital; R. Milne, London Hospital; R. H. Pettersson, St. George's Hospital; and J. M. Wall, St. Thomas's Hospital.

Midwifery.—R. Milne, London Hospital; L. F. Pain, Royal Free Hospital; and A. E. Pollitt, Manchester.

The Diploma of the Society was granted to the following candidates, entitling them to practise medicine, surgery, and midwifery:—J. Fox-Russell, H. M. Gray, and R. Milne.

UNIVERSITY OF DURHAM: FACULTY OF MEDICINE.—At the third examination for the degree of Bachelor of Medicine held recently the following candidates were successful:—

Materia Medica, Pharmacology and Pharmacy, Public Health, Medical Jurisprudence, Pathology and Elementary Bacteriology.—Percy Vernon Anderson, Richard Vere Brew, Hugh John Dingle, Donald Henegan, William Andrew Hewitson, Charles Gordon Irwin, George Malayramon Kerry, John Kerr Ritchie Landells, Sadek Abdel Shehid, Iskander Soliman, and Harold Ivan Sterne-Howitt.

CENTRAL MIDWIVES BOARD.—A meeting of the Central Midwives Board was held at Caxton House, Westminster, on March 16th, with Sir Francis H. Champneys in the chair. The Board had already considered a large number of suggestions for the amendment of the rules sent in by local supervising authorities, medical officers of health, examiners, and others; and, the revision being now completed, have decided to ask the Privy Council to approve the revision and to order that the new rules shall come into force on July 1st next, for a period of five years. A letter was considered from the General Medical Council with regard to an apparent case of "covering" an uncertified woman by a registered medical practitioner. The Board directed that the papers in the case be forwarded to the General Medical Council with a request that they will take such action in the matter as may seem fit to them, and that if so desired the Board will undertake to appear as prosecutors in the case. Letters were considered from the clerks to the Epsom and Chester boards of guardians asking that the Epsom Infirmary and the Chester Union Hospital may be treated as training schools, where a period of four months' training may be substituted for one of six months as provided for in the new rules. The Board directed that the clerks be informed that the Board has no power to grant the requests. A letter was considered from the medical officer of health of Liverpool asking whether under the new rule the conceded four months' period of training may be taken during the stipulated three years' training and may form part of such training. The Board decided that there is nothing in the rules to prevent the four months' midwifery training contemplated by the rule being taken during the three years' general training and forming a part of it.

LIVERPOOL MEDICAL INSTITUTION: JUBILEE OF MR. EDGAR A. BROWNE AND DR. GEORGE C. WALKER.—Fifty years' membership of the Liverpool Medical Institution is a notable record, and it is one on which the cordial congratulations of a large number of fellow members and professional colleagues were paid recently at a special meeting of the society, to Mr. Edgar Athelstane Browne, consulting surgeon to the Liverpool Eye and Ear Infirmary, and Dr. George Charles Walker, of Southport. The Lord Mayor was unfortunately prevented from attending the ceremony in order to tender the good wishes of the city to the two medical veterans. Dr. C. J. Macalister, the president of the institution, occupied the chair, and tendered a graceful tribute to the work and personality of both members, whose association with the society dated from the year 1866. Professor T. R. Glynn spoke of the ready wit and lively imagination of Mr. Edgar Browne, inherited from his distinguished father Hablot Browne. Dr. Richard Caton and Mr. T. H. Bickerton having both borne testimony to the personal qualities of the two members, a resolution setting forth their professional history, together with an expression of the kindly sentiments of their brethren on their interesting jubilee, was cordially adopted.

DONATIONS AND BEQUESTS.—The late Colonel H. L. Florence, V.D., has, among other bequests, left £10,000 each to St. Bartholomew's Hospital and Charing Cross Hospital. The residue of the estate, subject to two life-interests, amounting to about £100,000, is to be divided equally between St. Bartholomew's Hospital, Charing Cross Hospital, the National Gallery, and a number of other hospitals and museums.

THE MEDICAL PROFESSION AND MASSAGE ESTABLISHMENTS.—Under the provisions of the London County Council (General Powers Act), 1915 (Part V.), an establishment for massage or special treatment is defined as meaning any premises in the County of London used or represented as being or intended to be used for the reception or treatment of persons requiring massage, manicure, chiropody, light, electric, vapour, or other baths, or other similar treatment, and persons carrying on such establishments must be registered. Medical men are exempted, but they must comply with certain requirements in order to escape registration. These requirements have been the subject of discussion by the Council of the Metropolitan Counties Branch of the British Medical Association, and at a meeting held on March 14th resolutions were adopted to the following effect: (1) "That it is derogatory to the medical profession that a medical practitioner shall be required to furnish two certificates showing that the establishment for which he is responsible 'is not and will not be used for an immoral purpose'"; and (2) "that the terms of the Act in relation to medical practitioners are so widely drawn that no medical practitioner is wholly safe from certification or from inspection under the Act."

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

Reports of Medical Officers of Health.

IN the annual report of the Local Government Board for 1914–15 relating to Housing and Town Planning there is a reference to the reports of medical officers of health in the section devoted to housing conditions. The report states that upon the whole there has been a considerable improvement in the reports in the last few years, and there is fresh evidence that the increased interest in the matter taken by medical officers of health and inspectors of nuisances has a material influence for good in the consideration of the subject by the local authorities. There are, however, still cases in which the Board is unable to regard the reports as sufficient and has to ask for a supplementary report containing further and fuller information, but the number of such cases shows a decided tendency to diminish.

Financial Statement of the General Medical Council.

The annual return has been presented to Parliament of the receipts and expenditure of the General Medical Council and the Branch Councils.

An Extraordinary Incident.

The House of Commons on Wednesday afternoon was startled by an extraordinary incident. While a new Member was taking the oath at the table an officer in military uniform who had been sitting in the Strangers' Gallery climbed over into the Distinguished Strangers' Gallery. He scrambled over the rail and for a few moments hung to it by his hands. He then dropped some 20 feet or more on to the floor of the House. Falling heavily, he rose, and evidently addressing the Speaker, said: "Sir, I ask you to protect the heads of British soldiers from shrapnel fire." Members were amazed at the incident and at the rapidity with which it occurred. The officer was speedily conducted from the House. It was afterwards reported at Westminster that the was an officer in the Royal Army Medical Corps.

HOUSE OF COMMONS.

WEDNESDAY, MARCH 22ND.

Military Isolation Hospitals at Cambridge.

Mr. PAGET asked the Under Secretary for War whether his attention had been called to a resolution passed by the town council of the borough of Cambridge on Thursday, March 2nd, 1916, drawing the attention of the War Office to

the lack of control of, and to the insufficient guards placed at, the military isolation hospitals in Cherryhinton-road and Newmarket-road, whereby patients were enabled to escape and thereby cause danger to the health of the community; and would he say what steps he proposed to take in the matter.—Mr. TENNANT answered: This matter is already under the consideration of the Army Council. I cannot state to-day what steps it is proposed to take in the matter.

Tuberculous Soldiers and National Insurance.

Replying to Major ASTOR, Mr. C. ROBERTS (representing the National Insurance Commissioners) said: Approximately 2000 cases of tuberculous soldiers have passed through the hands of the several commissions in connexion with the arrangements made in April, 1915, for the provision of immediate residential treatment for discharged tuberculous soldiers and have been provided with treatment. In addition it is known that a large number of soldiers who became on or after discharge eligible for sanatorium benefit, have made application for the benefit direct to the local Insurance Committees, who have afforded treatment without reference to the Insurance Commissioners. The actual number of such cases, including, of course, many cases which arose before the special arrangements were established, could not be obtained without a special return from all Insurance Committees in the United Kingdom.

A College of Nursing.

Mr. HOGGE asked the President of the Board of Trade whether he had been asked to incorporate a college of nursing; whether he had received protests from societies of trained nurses, in particular the Scottish Society; and whether, in view of the Bill before Parliament prior to the war dealing with trained nurses, he proposed to do so.—Mr. RUNCIMAN replied: I have received certain protests against the grant of a licence to enable a college of nursing to be incorporated with limited liability without the addition of the word "Limited" to its name, including one from the Scottish Society of Trained Nurses. I have not yet received any application for such a licence.

Mr. HOGGE: If my right honourable friend receives an application will he bear in mind that there was a Bill before Parliament on the subject, and will he remember that fact in giving his decision?—Mr. RUNCIMAN: Yes, sir.

Pensions for Army Nurses.

Speaking during the debate on the motion for the second reading of the Consolidated Fund (No. 2) Bill, Mr. H. FORSTER (Financial Secretary to the War Office) said that at the outbreak of the war there was a system of pensions and disablement allowances for the army nursing staff. There were various qualifications as to length of service and so on. These were wholly inapplicable to present conditions. The War Office had taken steps to institute a special scale of pensions for those nurses who were disabled either by diseases, accident, or anything of the kind wholly and directly due to service or aggravated by service, and he hoped that the scale of pensions which had been framed would be sufficiently generous to meet the case. The matter had been discussed with the head of the nursing service, the matron-in-chief.

THURSDAY, MARCH 23RD.

Medical Arrangements in Mesopotamia.

Answering Mr. FELL, Mr. TENNANT (Under Secretary for War) said: Medical arrangements in Mesopotamia are primarily under the control of the military authorities in India, but the Commander-in-Chief in India has been informed that the Army Council would render him any assistance in medical personnel and equipment. All demands have been met without delay. 120 medical officers (including 40 from Egypt) and 205 other ranks, R.A.M.C., have arrived or are on their way. In addition, one British general hospital of 1040 beds and one British stationary hospital of 400 beds have been sent from Egypt. Both these units were fully equipped. Four Indian general hospitals of 500 beds each, which were in this country, have also been sent. Two of these were fully equipped and the remaining two consisted of personnel only. From France the Lahore Indian stationary hospital of 200 beds and 33 medical officers are under orders. A motor ambulance convoy—50 cars with complete personnel—is nearly ready and will leave for Mesopotamia early next month.

Colonel LOCKWOOD: Have any of them arrived?—Mr. TENNANT: I have not had any intimation to that effect.

Mr. MALCOLM asked the right honourable gentleman since what dates all military and medical questions connected with the British expedition to Mesopotamia had been taken over by the War Office.—Mr. TENNANT answered: The new arrangements for the control of operations in Mesopotamia came into force from Feb. 16th, 1916. The Commander-in-Chief in India receives instructions from the Chief of the Imperial General Staff in exactly the same manner as the commanders-in-chief in other theatres, but India remains the main base of the forces in Mesopotamia which is administered by the Commander-in-Chief in India. Such requirements of the force as India cannot meet are supplied by the War Office from other parts of the Empire so far as considerations of general policy do not render this impracticable.

Mr. MALCOLM asked whether Sir William Vincent and General Bingley had proceeded to Mesopotamia to conduct the inquiry into the alleged breakdown of medical arrangements.—Mr. TENNANT said in reply: The Commission, after taking evidence in Bombay, left for Mesopotamia on March 10th. Sir William Vincent is a man of wide administrative experience and has proved efficient in high and responsible official posts, and Major-General Bingley has had a great deal of staff experience and is well suited for an inquiry into the alleged deficiencies in the organisation of supplies. I think these gentlemen are amply qualified to elucidate the facts and to make a fair, complete, and judicial report upon them, having reference to all aspects of the question. They can procure any technical and expert evidence they desire.

Lord HENRY CAVENDISH-BENTINCK asked the Secretary for India whether up to five weeks ago repeated offers made by several hospital supply depôts to send out large quantities of hospital supplies to Mesopotamia were refused; and if so, would he say by whom these offers were refused, and whether he would cause an inquiry to be made into the cause of the breakdown of the hospital arrangements in Mesopotamia.—Mr. CHAMBERLAIN (in a written answer) replied: I have been informed since this question appeared on the paper that the Joint War Committee of the British Red Cross Society and the Order of St. John of Jerusalem in coöperation with the Indian Soldiers' Fund offered their general assistance direct to the general officer commanding Mesopotamia in July last, and repeated their offers at later dates; that stores were sent by them to Basra in September, two motor loads in August and another in October. In December I transmitted further offers on their behalf. On Jan. 31st last the following offer was made officially by the committee to the India Office. They offered to place at my disposal the organisation of the two societies to supplement the provision made by the Indian Government for the care of sick and wounded in Mesopotamia. The offer was in the widest and most generous terms, but referred in particular to the possibility of help in the supply of stores, of clothing, medical comforts, drugs, and luxuries not included in the scheduled army lists, in the supply of barges, motor ambulances, and other vehicles for the transport of the sick and wounded, and in the equipment of hospitals and in providing personnel to staff and administer such hospitals. I immediately communicated this generous offer to the Viceroy. Before replying he had to ascertain that it would not conflict with the organisation and arrangements of similar Indian societies, but on Feb. 19th he informed me that the Indian Council of St. John Ambulance, which from the outset had actively concerned itself with the Mesopotamia Force, would gladly accept the assistance. I communicated the Viceroy's reply the same day to the Joint War Committee. As regards other societies, the Indian Soldiers' Fund in October made inquiry through me of the military authorities in Mesopotamia as to whether clothing and comforts were needed for the troops, and was informed by them in reply that for the present the supply from India was sufficient. I understand that the Fund Committee at that time had independent evidence that there were sufficient supplies at the base. In December I received from the fund and transmitted to the Viceroy an offer to supply bandages, surgical dressings, and other medical and hospital comforts. The Viceroy gladly accepted it and early in January a large contribution of articles, some of which were contributed by the Joint War Committee, was despatched to Mesopotamia. Besides the offers which were made through me and those made independently of me, to which I have already referred, many offers of which I have no knowledge may have been made direct to corresponding societies in India which were engaged in providing comforts for the combatants and medical supplies for the hospitals. I understand that the Indian Branch of St. John Ambulance has from the first taken a very active part in providing for the medical needs of the force. With regard to the last part of the question, I would refer my noble friend to the statement which I made yesterday.

The Organisation of the R.A.M.C.

Sir PHILIP MAGNUS asked the Under Secretary for War whether any and, if so, what steps had been taken to arrange that doctors with special experience in different branches of medicine and surgery who had joined the Royal Army Medical Corps were being so employed by the War Office as to utilise to the best advantage their special qualifications:—Mr. TENNANT answered: I can assure the honourable gentleman that every effort is made to employ gentlemen who join the Royal Army Medical Corps in such a way as to give their individual qualifications every consideration. But I must at the same time point out that it is sometimes not practicable to use their services exclusively in one special line of practice, as the need for special work is limited. My

information is that these gentlemen willingly give their attention to work outside their special qualifications when work of that kind is awaiting attention.

Sir PHILIP MAGNUS asked whether the Government would consider the advisability of reconstituting the Advisory Board to coöperate with the general superintendent in the further organisation of the medical service; and, if so, whether he would have regard to the suggestion that had been made by a number of medical men that such a board should consist of some lay representatives.—Mr. TENNANT replied: I take note of the honourable Member's suggestion, but I cannot admit that a case has been made out for interfering with the organisation as it at present exists.

Mr. R. MCNEILL: Is it not a fact that the Advisory Board was, in point of fact, in existence when the war broke out and that neglect to call it together was without any proper authority whatever?—Mr. TENNANT: No, sir, I think my honourable friend is misinformed as to the facts. I did give him a description of what occurred at the beginning of the war in the debate the other evening. It was quite within the competence of the military authorities to suspend the activities of the Advisory Board as and when they might think proper, but I think it is true that the Board had been sitting up to that time.

Sir PHILIP MAGNUS asked whether the right honourable gentleman could see his way to utilise to a greater extent the services, in part-time work at hospitals or in looking after the health of troops, of medical practitioners resident in the neighbourhood, and by so doing to release a proportion of the men who had volunteered for whole-time service abroad or had been asked to take commissions in the Royal Army Medical Corps.—Mr. TENNANT wrote in reply: The policy suggested in the question is already followed. There is now a considerable number of medical practitioners employed in part-time work, and it is anticipated that this number will be largely increased.

Venereal Disease.

Colonel LOCKWOOD asked the Prime Minister whether it was the intention of the Government to adopt the Report of Lord Sydenham's Commission on Venereal Diseases; and, considering that history showed a recrudescence of such disease at the end of every great war, whether he would take steps to put into immediate action the recommendations of this Commission.—Mr. LLOYD GEORGE (on behalf of Mr. ASQUITH) replied: The recommendations of the Royal Commission are now under consideration.

Steel Helmets for the Troops.

Answering Sir D. GODDARD and Sir I. HERBERT, Mr. LLOYD GEORGE (Minister of Munitions) said that reports of a very satisfactory nature had been received on the steel helmets for the troops, and the necessary steps had been taken to obtain a supply sufficient to meet the requirements of the War Office. More than 300,000 had already been delivered. A satisfactory pattern was approved some five months ago and changes were being made to meet the improvements suggested by experience.

TUESDAY, MARCH 28TH.

Medical Arrangements in Mesopotamia.

Mr. R. GWYNNE asked the Under Secretary for War whether, when the shortage of doctors and nurses and hospital equipment for the forces in Mesopotamia was realised by the Government, any endeavour was made to transfer some of the hospital equipment in Egypt, and at present not being used, and so to secure aid to those wounded who were dying for want of attention.—Mr. TENNANT answered: Yes, sir. Aid was offered as soon as it was realised that aid was wanted.

Mr. GWYNNE asked the Secretary for India whether offers of hospital supplies for Mesopotamia were made by hospital supply depôts three months ago to the proper authorities, which offers were renewed from time to time, but were refused on the plea of sufficiency and that India had more than enough for all eventualities.—Mr. CHAMBERLAIN wrote in reply: The Government of India are responsible for the equipment of all forces coming from India, the War Office for those coming from Europe. Supply is arranged by the Government of India in communication with the India Office or the War Office, according to the nature of the supply.

Venereal Disease in Army in Egypt.

Colonel LOCKWOOD asked the Under Secretary for War to state how the recent figures given regarding admission ratio per 1000 for venereal disease in Egypt compare with the years 1913, 1914, and 1915.—Mr. TENNANT replied: The annual admission ratio per 1000 of strength for the years mentioned was: 1912, 110·8; 1913, 117·7; 1914 (first eight months), 140·4. I gave my honourable and gallant friend the figure 46·8 per 1000 for the eight weeks ending March 20th, 1916. The figures for 1915 are not available.

Payments for Examining Recruits.

On the third reading of the Consolidated Fund (No. 3) Bill, Mr. KENDALL called attention to the remuneration paid to medical men for examining recruits. During the time of the Derby campaign some medical men worked 16 hours a day and dealt with as many as 200 or 300 recruits a day. It was unfair that the rate of remuneration should have been only £2 a day, the same as was paid to medical men who only worked for six hours and examined 40 recruits.—Mr. H. FORSTER (Financial Secretary to the War Office) said that the instructions issued by the War Office as to the amount of work that should be done in a day were directed to get some real kind of medical examination. The medical authorities at the War Office were consulted as to the number of men who might reasonably be examined with some searching care in the course of six hours. The reply of the medical authorities was that a medical man might be properly expected to examine something like 40 men. The War Office did not want excessive numbers to be examined at a time. It became clear when the great rush of recruits came that a medical examination on the latter lines was so rushed as to be imperfect and worthless. Such hurried examinations had to be done over again. In the last days of the Derby rush there was no question of losing recruits. The men having been registered could subsequently be called up for medical examination.

Appointments.

Successful applicants for vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward to THE LANCET *Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, such information for gratuitous publication.*

BAKER, MADELEINE STUART, M.D., B.Ch., B.A.O. Dub., has been appointed Deputy Acting School Medical Officer for the Bristol Education Committee.

LAM, PING WING, M.B., Ch.B. Edin., has been appointed Resident Medical Officer to the Leicester Board of Guardians.

PEACHELL, GEORGE ERNEST, M.D., B.S Lond., L.R.C.P., M.R.C.S., has been appointed Medical Superintendent at the Dorset County Asylum.

ROBERTS, H. S. W., L.R.C.P. & S. Edin., has been appointed Certifying Surgeon under the Factory and Workshop Acts for the Ballindalloch District of the county of Banff.

Vacancies.

For further information regarding each vacancy reference should be made to the advertisement (see Index).

When the application of a Belgian medical man would be considered the advertisers are requested to communicate with the Editor.

BELGRAVE HOSPITAL FOR CHILDREN, Clapham-road, S.W.—Resident Medical Officer for six months. Salary at rate of £100 per annum, with board, residence, and washing.

BIRMINGHAM AND MIDLAND EYE HOSPITAL, Church-street.—Resident Surgeon.

BOLTON INFIRMARY AND DISPENSARY.—Female Second House Surgeon and Female Third House Surgeon. Salary £200 and £180 per annum respectively, with apartments, board, and attendance.

BRISTOL GENERAL HOSPITAL.—Casualty House Surgeon. Also House Physician. Both for six or three months. Salary at rate of £175 per annum each, with board, residence, &c.

BRISTOL ROYAL INFIRMARY.—House Physicians and House Surgeons. Salary at rate of £120 per annum, with board, apartments, and laundry.

BURNLEY, VICTORIA HOSPITAL.—Female House Surgeon. Salary £160 per annum, with residence, board, and washing.

CHARING CROSS HOSPITAL.—Resident Medical Officer.

CHESTERFIELD AND NORTH DERBYSHIRE HOSPITAL.—Second House Surgeon. Salary £150 per annum, with board, apartments, and laundry.

DORSET COUNTY COUNCIL.—Temporary Female Assistant Medical Officer. Salary at rate of £300 per annum.

DUDLEY, GUEST HOSPITAL.—Assistant House Surgeon for six months. Salary £120 per annum, with board, residence, and washing.

DURHAM COUNTY HOSPITAL.—House Surgeon. Salary £150 per annum, with board, lodging, &c.

EAST HAM COUNTY BOROUGH EDUCATION COMMITTEE.—Temporary Female Assistant School Medical Officer. Salary £300 per annum.

EXETER, ROYAL DEVON AND EXETER HOSPITAL.—Senior House Surgeon. Salary at rate of £250 per annum, with board, apartments, and washing.

GLASGOW, ROYAL SAMARITAN HOSPITAL FOR WOMEN.—Female Muirhead Scholarship for Clinical and Pathological Research. Value £50 per annum. Also Pathologist.

GREAT NORTHERN CENTRAL HOSPITAL, Holloway-road, N.—House Physician for six months. Salary at rate of £100 per annum, with board, residence, and laundry.

GUILDFORD, ROYAL SURREY COUNTY HOSPITAL.—House Surgeon. Salary £150 per annum, with board, residence, and laundry.

HALIFAX COUNTY BOROUGH EDUCATION COMMITTEE.—Assistant Medical Officer. Salary £350 per annum.

HUDDERSFIELD ROYAL INFIRMARY.—Junior House Surgeon. Salary £100 per annum, with board, residence, and laundry.

LONDON HOMŒOPATHIC HOSPITAL, Great Ormond-street, W.C.—House Surgeon. Also Two Resident Medical Officers. Salary at rate of £100 per annum, with board, apartments, and laundry.

LONDON TEMPERANCE HOSPITAL, Hampstead-road, N.W.—Assistant House Surgeon for six months. Salary at rate of 120 guineas per annum.

LEEDS PUBLIC DISPENSARY.—Female Resident Medical Officer. Salary £130 per annum, with board, residence, and laundry.

MANCHESTER CHILDREN'S HOSPITAL, Pendlebury, near Manchester.—Two Female Resident Medical Officers for six months. Salary at rate of £100 per annum.

NEW HOSPITAL FOR WOMEN, Euston-road, N.W.—Female Radiographer. Salary £30 per annum. Also Female Assistant Pathologist. Salary £100 per annum. Also Female Senior Clinical Assistant to Out-patient Department.

NORWICH, NORFOLK AND NORWICH HOSPITAL.—House Physician. Salary £400 per annum, with board, residence, and laundry.

PUTNEY HOSPITAL, Putney Common, S.W.—Resident Medical Officer. Salary £150 per annum, with rooms, board, and laundry.

QUEEN'S HOSPITAL FOR CHILDREN, Hackney-road, Bethnal Green, E.—House Surgeons for six months. Salary £100 per annum, with board, residence, and washing. Also Temporary Medical Officer. Attendance once a week. £12 10s. per annum to cover travelling expenses.

ROCHESTER, ST BARTHOLOMEW'S HOSPITAL, Kent.—Senior Resident House Surgeon. Salary at rate of £300 per annum.

ROYAL FREE HOSPITAL, Gray's Inn-road, W.C.—Male and Female House Physicians and House Surgeons for six months. Salary £50 per annum, with board, lodging, and washing.

SALISBURY GENERAL INFIRMARY.—House Surgeon and Assistant House Surgeon. Salary £150 and £100 per annum respectively, with apartments, board, lodging, and washing.

SHEFFIELD ROYAL INFIRMARY.—House Surgeon. Salary £100 per annum, with board and residence.

SOUTHAMPTON FREE EYE HOSPITAL.—House Surgeon. Salary £100 per annum, with board, lodging, and laundry.

THROAT HOSPITAL, Golden-square W.—Honorary Medical Registrar.

WESTMORLAND CONSUMPTION SANATORIUM AND HOME, Grange-over-Sands.—Second Assistant. Salary £200 per annum, with apartments, board, and laundry.

WOUNDED ALLIES RELIEF COMMITTEE, Sardinia House, Kingsway, W.C.—Assistant Surgeon for British Hospital in France for French Wounded. Salary 5 guineas a week.

THE Chief Inspector of Factories, Home Office, London, S.W., gives notice of vacancies for Certifying Surgeons under the Factory and Workshop Acts at Newport, in the county of Mayo; and at East Grinstead, in the county of Sussex.

Births, Marriages, and Deaths.

BIRTHS.

BLOOD.—On March 23rd, at Brynland-avenue, Bishopston, Bristol, to Dr. and Mrs. B. N. Blood, a daughter.

HARE.—On March 22nd, at the Imperial Nursing Home, Cheltenham, the wife of Captain Theodore Hare, R.A.M.C., of a son.

LAMPLOUGH.—On March 25th, at Bredon, Alverstoke, the wife of Wharram H. Lamplough, M.D. Durh., temporary R.A.M.C., of a daughter.

MARRIAGES.

ASPLEN—O'DONNELL.—On March 15th, at St. Stephen's Church, Cheltenham, William Reginald Ward Asplen, Lieutenant, R.A.M.C., to Kate Norah, only daughter of the late Colonel A. C. O'Donnell, Indian Army, and Mrs. O'Donnell, of Maryville, Tivoli-road, Cheltenham.

OWEN—BOND.—On March 20th, at the Pro-Cathedral, Clifton, Ambrose W. Owen, M.D., B.S. Lond., late temporary Lieutenant, R.A.M.C., of Porth, Glam., to Beatrice Nina Bond, of Bridgwater, Somerset.

WAUGH—PICKERSGILL.—On March 27th, at Christ Church, Sunderland, William Grant Waugh, Captain, R.A.M.C., to Enid, only daughter of the late Charles Pickersgill and Mrs. Pickersgill, of The Elms North, Sunderland.

WHITE—MACKLIN.—On March 1st, at the British Legation, Teheran, Persia, Henry White, M.R.C.S., L.R.C.P. Lond., to Alice Martha, eldest daughter of Mr. and Mrs. Alfred Charles Macklin, of Ingleside, Wickham-road, Brockley, Kent.

DEATHS.

HARPER.—On March 24th, at Rosary-gardens, South Kensington, James Harper, M.D. Lond., Colonel, R.A.M.C. (T.), aged 58 years.

HEBBERT.—On March 19th, of relapsing fever, in Mesopotamia, Robert Francis Hebbert, Captain, I.M.S., aged 33 years.

PRICE.—On March 29th, at Hooper's Hill House, Margate, William Price, M.D., last surviving son of David Price, M.D., of Margate, aged 79 years.

N.B.—A fee of 5s. is charged for the Insertion of Notices of Births, Marriages, and Deaths.

BOOKS, ETC., RECEIVED.

ADLARD AND SON, London.
Cleft Palate and Hare-Lip. By Sir W. Arbuthnot Lane, Bart., M.S., F.R.C.S. Third edition. Price 10s.

CHURCHILL, J. AND A., London.
A Handbook of Colloid Chemistry. By Dr. Wolfgang Ostwald (Leipzig). Translated from the third German edition by Dr. Martin H. Fischer (Cincinnati), with the assistance of R. E. Vesper, Ph.D., and L. Berman, M.D. Price 12s. 6d. net.

LEWIS, H. K., London.
The Adolescent Period. By Louis Starr, M.D., LL.D. Price 4s. 6d. net.

MALOINE, A., ET FILS, 27, Rue de l'Ecole de Médecine, Paris.
La Gangrène Gazeuse et les Plaies Gangréneuses. Par les Drs. P. Moiroud et H. Vignes. Premier fascicule. Price 1.60fr.

OCEANA PRESS, Calle Chile, 525, Buenos Aires
Anatomia de los Conductos Biliares y de la Arteria Cistica. By Dr. Pedro Belou, Professor Titular de Anatomia Descriptiva de la Facultad de Ciencias Médicus de Buenos Aires.

Notes, Short Comments, and Answers to Correspondents.

THE VITAL STATISTICS OF THE LEEWARD ISLANDS.

IN his report for the year 1914-15 Mr. T. A. V. Best, the Colonial Secretary of the Leeward Islands of the West Indies (Antigua, St. Kitts-Nevis, Dominica, Montserrat, and the Virgin Islands), states that the total population of the colony, according to the last Census, was 127,193. The general health of the inhabitants during the year was good. The total number of patients admitted into the hospitals of the colony was 3713, as against 3827 in the previous year, whilst the number of deaths was only 266, as against 354. In the Leper Asylum at Antigua there were 39 lepers. The central lunatic asylum had 128 patients. The Alexandra Cottage Home for Incurables, Dominica, maintained on an average 10 paupers. In the Yaws Hospital at St. Kitts 177 patients were treated, all of whom were discharged as cured. Treatment had to be suspended and the ward closed for a time, as salvarsan, being a German preparation, was not procurable. The average rainfall from January to December, 1914, on 72 stations in Antigua was 36·86 inches, or 7·39 inches below the average of the 40 preceding years. The highest maximum temperature was 91° F. on Oct. 27th and Nov. 8th, and the lowest minimum temperature 66° on Jan. 7th. Three shocks of earthquake were recorded.

THE PUBLIC SCHOOLS YEAR BOOK.

THE twenty-seventh annual issue of this useful guide, edited by H. F. W. Deane, M.A., F.S.A., and W. A. Bulkeley Evans, M.A. (London: The Year Book Press, 31, Museum-street, W.C. Pp. 767. Price 5s. net) contains in a form handy for reference information relative to the governing bodies, staff, nomination and admission, entrance examination and scholarships, houses and dormitories, organisation and instruction, fees, charges, and prizes at the public schools, and details of the entrance examinations to the Universities. The conditions of admission to the Civil Service and other professions are included, and the sections devoted to the navy and army give the new regulations for temporary and permanent commissions. A list of preparatory schools, a public schools, bibliography, and short articles on the various professions are other useful features of the work. As the official reference book of the headmasters' conference it summarises the work of the committee of this conference. An invaluable work of reference for parents.

CHILDREN'S COUNTRY HOLIDAYS FUND.

Mr. Francis Morris, chairman of the Executive Committee, writes to say that the work of the Children's Country Holidays Fund is being carried on despite the war, and that donations are needed in order to send away the 18,000 to 20,000 children with whom it is hoped to deal this year. Efforts are being made to seek out the most ailing children in the elementary schools of London in order to provide them with a summer fortnight in country cottages. This work should appeal to all who have at heart the welfare of the growing generation.

HEALTH OF MAURITIUS.

A CORRESPONDENT writes:—In connexion with your note last week on the public health of Mauritius attention may be drawn to the meteorological observations taken at the Royal Alfred Observatory, Pamplemousses, and at nine second-order stations. The observatory is about three miles from the West Coast, and is 179 feet above sea level. There are considerable variations both in temperature and humidity in the different parts of the island, the coast districts being hotter and drier than the higher altitudes in the interior. Hurricanes occur between December and April, which is the hottest season. The mean rainfall at 49 stations was 59·10 inches as compared with 75·83 inches in 1913 and an average of 74·94 inches. Heavy rains, relatively to the normal, fell in February and June. The rainfall at the observatory was below normal, being 43·12 inches as compared with a normal of 47·95 inches, and the number of rainy days recorded was 215, as compared with an average of 204, a "rainy day" being one in which ·005 inch or more of rain was measured. The mean temperature of the air at the observatory was 73·7° F. as compared with an average of 73·4°, the highest temperature recorded being 89·9° on March 10th, and the lowest 54° on July 23rd. The highest and lowest temperatures recorded at the observatory between 1875 and 1914 were 94·7° on Dec. 23rd, 1900, and 49·9° on August 8th, 1907. From February to September the temperature remained generally above normal, falling to below normal in the last quarter of the year.

Medical Diary for the ensuing Week.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street. W.

MEETINGS OF SECTIONS.

Friday, April 7th.

LARYNGOLOGY (Hon. Secretaries—Cecil Graham, Frank Rose): at 4 P.M.

Dr. L. H. Pegler: Case of Laryngeal Tuberculosis.

Mr. E. D. D. Davis: (1) Report of a Case of Laryngeal Crises, with Abductor Paralysis (Sections of the Brain, Spinal Cord, and Vagus Nerves will be demonstrated); (2) Laryngeal Stenosis following a Bayonet Wound treated by Intubation.

Mr. Herbert Tilley: Cases illustrating Results of Intranasal Operation for Chronic Frontal Sinusitis.

Dr. James Donelan: Case of Paralysis of Left Vocal Cord in a Young Woman.

Dr. Jobson Horne: Two Cases of Suppuration in the Antrum of Highmore due to Uncommon Causes.

And other Cases.

RÖNTGEN SOCIETY, Institution of Electrical Engineers, Victoria Embankment, W.C.

TUESDAY.—8.15 P.M., General Meeting. Demonstration:—Mr. P. J. Neate:—A Chronograph constructed to Work with the Electroscope. Papers:—Mr. B. H. Morphy and Mr. S. R. Mullard: The Enclosed Tungsten Arc as a Source of Ultra Violet Light.—Mr. E. Schall: Experiments with a Coolidge Tube.—Mr. H. E. Donnithorne: A New Modification of the Ionization Method of Measuring X Rays. Exhibition of Plates showing Experiments with the Coolidge Tube in Radiography, conducted by Members of the Staff in the Radiographic Department at the Cancer Hospital.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY, West London Hospital, Hammersmith-road, W.

FRIDAY.—8 P.M., Special Clinical Evening.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East.

TUESDAY AND THURSDAY—5 P.M., Lumleian Lectures:—Dr. F. E. Batten: Acute Poliomyelitis. (Lectures II. and III.)

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.

Course of Lectures on the Anatomy of the Human Body, for First-aid and Ambulance Students (open to all members of ambulance companies and first-aid classes):—

MONDAY, WEDNESDAY, AND FRIDAY.—5.30 P.M., Prof. A. Keith. 4 P.M. to 7 P.M., Exhibition of Anatomical Preparations and Specimens in the Theatre on lecture days, and between 10 A.M. and 5 P.M. in the Hall of the Museum on the following day.

POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.

MONDAY.—2 P.M., Medical and Surgical Clinics. X Rays. Mr. Gray: Operations. Mr. B. Harman: Diseases of the Eye. Dr. Simson: Diseases of Women.

TUESDAY.—2 P.M., Medical and Surgical Clinics. X Rays. Mr. Addison: Operations. Dr. Banks Davis: Diseases of the Throat, Nose, and Ear. Dr. Pernet: Diseases of the Skin.

WEDNESDAY.—10 A.M., Dr. Saunders: Diseases of Children. Dr. Banks Davis: Operations of the Throat, Nose, and Ear. 2 P.M., Medical and Surgical Clinics. X Rays. Mr. Pardoe: Operations. Dr. Simson: Diseases of Women.

THURSDAY.—2 P.M., Medical and Surgical Clinics. X Rays. Mr. Gray: Operations. Mr. B. Harman: Diseases of the Eye.

FRIDAY.—10 A.M., Dr. Simson: Gynæcological Operations. 2 P.M., Medical and Surgical Clinics. X Rays. Mr. Addison: Operations. Dr. Banks Davis: Diseases of the Throat, Nose, and Ear. Dr. Pernet: Diseases of the Skin.

SATURDAY.—10 A.M., Dr. Saunders: Diseases of Children. Dr. Banks Davis: Operations of the Throat, Nose, and Ear. Mr. B. Harman: Eye Operations. 2 P.M., Medical and Surgical Clinics. X Rays. Mr. Pardoe: Operations

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY.—Clinics:—10.30 A.M., Surgical Out-patients (Mr. E. Gillespie). 2.30 P.M., Medical Out-patients (Dr. T. R. Whipham): Gynæcological Out-patients (Dr. Banister). 3 P.M., Medical In patients (Dr. R. M. Leslie).

TUESDAY.—2.30 P.M., Surgical Operations (Mr. Carson). Clinics:—Medical Out-patients (Dr. A. G. Auld); Surgical Out patients (Mr. Howell Evans); Nose, Throat, and Ear Out-patients (Mr. C. H. Hayton). Radiography (Dr. Metcalfe). 3.30 P.M., Medical In-patients (Dr. A. J. Whiting).

WEDNESDAY.—Clinics:—2.30 P.M., Throat Operations (Mr. C. H. Hayton). Children Out-patients (Dr. T. R. Whipham); Eye Out-patients (Mr. R. P. Brooks); Skin Out-patients (Dr. H. W. Barber). 5.30 P.M., Eye Operations (Mr. R. P. Brooks).

THURSDAY.—2.30 P.M., Gynæcological Operations (Dr. A. E. Giles). Clinics:—Medical Out-patients (Dr. A. J. Whiting); Surgical Out-patients (Mr. Carson); Radiography (Dr. Metcalfe). 3 P.M., Medical In patients (Dr. R. M. Leslie).

FRIDAY.—2.30 P.M., Surgical Operations (Mr. Howell Evans). Clinics:—Medical Out-patients (Dr. A. G. Auld); Surgical Out-patients (Mr. E. Gillespie); Eye Out-patients (Mr. R. P. Brooks).

THE THROAT HOSPITAL, Golden square, W.

MONDAY.—5.15 P.M., Special Demonstration of Selected Cases.

THURSDAY.—5.15 P.M., Clinical Lecture.

For further particulars of the above Lectures, &c., see Advertisement Pages.

METEOROLOGICAL READINGS.

The following magazines, journals, &c., have been received:—

American Journal of Surgery, American Journal of Roentgenology, Canadian Practitioner and Review, Proceedings of the Royal Society of Medicine, Pacific Medical Journal, Interstate Medical Journal, Indian Medical Record, Calcutta Medical Journal, Royal London Ophthalmic Hospital Reports, &c.

EDITORIAL NOTICES.

IT is most important that communications relating to the Editorial business of THE LANCET should be addressed *exclusively* "TO THE EDITOR," and not in any case to any gentleman who may be supposed to be connected with the Editorial staff. It is urgently necessary that attention should be given to this notice.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this office.

Lectures, original articles, and reports should be written on one side of the paper only, *and when accompanied by blocks it is requested that the name of the author, and if possible of the article, should be written on the blocks to facilitate identification.*

Letters, whether intended for insertion or for private information, must be authenticated by the names and addresses of their writers—not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or news paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale, and advertising departments of THE LANCET should be addressed "To the Manager."

We cannot undertake to return MSS. not used.

MANAGER'S NOTICES.

TO SUBSCRIBERS.

WILL Subscribers please note that only those subscriptions which are sent direct to the Proprietors of THE LANCET at their Offices, 423, Strand, London, W.C., are dealt with by them? Subscriptions paid to London or to local newsagents (with none of whom have the Proprietors any connexion whatever) do not reach THE LANCET Offices, and consequently inquiries concerning missing copies, &c., should be sent to the Agent to whom the subscription is paid, and *not* to THE LANCET Offices.

Subscribers, by sending their subscriptions direct to THE LANCET Offices, will ensure regularity in the despatch of their Journals and an earlier delivery than the majority of Agents are able to effect.

THE COLONIAL AND FOREIGN EDITION (printed on thin paper) is published in time to catch the weekly Friday mails to all parts of the world.

ALTERATION OF INLAND SUBSCRIPTION RATES.

OWING to the alteration in the Inland Newspaper Postal rate, the postage on each copy of THE LANCET will in future be 1*d.*, and sometimes 1½*d.*

The revised Inland Subscription rates are:—

One Year	£1 3 3
Six Months	0 13 8
Three Months	0 7 0

The rates for the Colonies and Abroad (thin paper edition) will be as usual:—

One Year	£1 5 0
Six Months	0 14 0
Three Months	0 7 0

Subscriptions (which may commence at any time) are payable in advance. Cheques and Post Office Orders (crossed "London County and Westminster Bank, Covent Garden Branch") should be made payable to the Manager, Mr. CHARLES GOOD, THE LANCET Offices, 423, Strand, London, W.C.

TO COLONIAL AND FOREIGN SUBSCRIBERS.

Subscribers abroad are particularly requested to note the rates of subscriptions given above.

The Manager will be pleased to forward copies direct from the Offices to places abroad at the above rates, whatever be the weight of any of the copies so supplied.

NEWSPAPERS FOR NEUTRAL COUNTRIES.

Newspapers are not at present being sent forward to neutral European countries unless posted direct from the office of publishers or newsagents who have obtained permission from the War Office for this purpose. The Publisher of THE LANCET has obtained the required permission, and he will forward copies direct from the Office to any neutral country on receipt of instructions.

ADVERTISEMENT RATES.

A Report
ON
THE USE OF STOCK VACCINE IN INFECTION BY THE BACILLUS TYPHOSUS.
WITH AN ANALYSIS OF 230 CASES.

BY T. H. WHITTINGTON, M.D. LOND.,
CAPTAIN, R.A.M.C. (T.C.)

THE 230 cases under consideration were in hospital during the winter 1914–15. Half the cases were in my medical charge, the remainder being in the wards of Major D. P. Johnstone, Captain J. A. Torrens, Captain G. D. H. Wallace, and other medical officers. Careful notes were taken and a summary of each case was made at its termination by the particular medical officer, and I am much indebted to them.

Methods Adopted in the Investigation.

The notes of the cases were made on the same plan, which was carried out with various modifications by the other officers. At the end of the winter, with the cases fresh in mind, an analysis was made of my series. About 500 cases of the enteric group have now passed through my wards, and after this additional clinical experience an attempt has been made to judge the effects of vaccine and to reconsider all the typhoid cases which have had this treatment.

To be certain of the effects of vaccine in any particular case is a difficult matter, as mere impressions in isolated cases often prove false. Vaccine given to a patient in the hope that it will do good is liable to get the credit of his excellent recovery, when there is no actual proof that he would not have done equally well without it. How, then, is one to judge the effects? It is obvious that even if a scientifically accurate method were available carefully selected controls are necessary, and that impressions have to be checked by a comparison between the vaccinated cases and the unvaccinated controls, and that *groups* of the same kind of case should be compared with other control groups.

Altogether 176 cases have had vaccine treatment. The cases now considered number 230; half of these were on vaccine treatment and the other 115 are the selected controls. To make a just comparison between the two sets of cases has been the object of this investigation. The analysis of the cases incidentally shows what were the usual course and complications of the disease among the soldiers in this hospital during the winter 1914–15.

The selection of the cases.—In order that cases of typhoid may be rightly compared they must conform to certain standards. It was by a rigid conformity to these standards that the cases were reduced in number to 230. First, it must be certain that all the cases are *true* typhoid and not merely due to one or other of the three organisms of the enteric group. For this reason neither the expression "typhoid fever" nor "enteric fever" was used in the title of this paper, as both these terms are often applied clinically to any case of the enteric group. Paratyphoid is, in the great majority of cases, a much milder disease than typhoid, the average prognosis being better in every way and the death-rate much lower.[1] In the early days of this hospital there had not been time or material to put the laboratory into proper working order. Many cases, therefore, were considered "typhoid fever" on clinical grounds or after the isolation from them of a Gram-negative motile bacillus which did not ferment lactose. Several such cases were treated with vaccine, and, making a good and rapid recovery, were considered at the time good results for this treatment. Further investigation of the organisms from some of these patients proved that the disease had been paratyphoid, and, as one came to recognise the usual course of this disease it was seen that these so-called good results were fallacies (see Case 0).

It is with this memory of some of our earlier mistakes that I place the bacteriological proof of the cases as the first essential. The hospital has been most fortunate in having several bacteriologists thoroughly acquainted with the bacilli of the enteric group. It is especially due to the work of Captain J. L. Wood, R.A.M.C., and of Captain W. H. Tytler, C.A.M.C., that the cultures of the organisms obtained from the cases are now in the laboratory, each indexed with a full account of their reactions and of the stringent standards to which they had to conform before being finally named. An analysis would have been useless without this sure foundation of the accurate bacteriological diagnosis of the cases. Of the 230 cases, 205 had the bacillus typhosus isolated from them. Of these, 177 were isolated from the blood stream, 20 from the stools, and 8 from the urine. In 43 of the fatal cases a post-mortem examination was made, and in 26 of the cases B. typhosus was isolated from the gall-bladder, and in 8 from the spleen. The remaining 25 cases, from which the organism was not isolated, were identified by the fact that their serum agglutinated B. typhosus before vaccine was given, and as all were uninoculated this seems sufficient. All cases in which the laboratory evidence was incomplete or equivocal or suggested a double infection have been excluded. Cases sent in as bacteriologically diagnosed "enteric" or "typhoid" are not necessarily included, as often all that was meant was that one of the organisms of the enteric series had been isolated.

The state of inoculation complicates the question of typhoid among soldiers. One cannot properly compare the effect of vaccine in unprotected cases with that in cases which already have had some variable amount of protection given them by the use of the same vaccine. Also serious cases are rare among inoculated men, and thus only a few inoculated cases have been treated by vaccine at this hospital. For these reasons I have paid special attention to the uninoculated cases. Of the series, 200 are of this kind—100 treated with vaccine and 100 unvaccinated controls. A few cases have been included in which the protective inoculation was given during the apparent onset of the disease (Case 164).

The varying severity of the disease in individuals and the fact that some cases come under treatment late and others early in the course of their fever make comparisons difficult. In analysing the cases I have divided them into classes according to their apparent severity at the time of admission and into groups according to the prognosis. Similar classes and groups of cases can then be compared according as they have or have not been on vaccine treatment. It is well known that typhoid varies not only in its incidence but also in its severity according to the year and season of the year, the climate and

[1] Torrens and Whittington: The Clinical Aspects of Paratyphoid Fever, Brit. Med. Jour., Nov. 13th, 1915, and Journal of the R.A.M.C., October, 1915.

locality, and the age and sex, and that the incidence of the complications is much affected by these factors. To judge the results of a method of treatment of any infectious disease, but especially of typhoid, the above conditions should be constant. The cases now considered occurred between November and May, the great majority during the months of December to March inclusive. They came from the comparatively small area occupied at the time by the troops of the Expeditionary Force. Finally, the patients all being soldiers, age and previous health were fairly constant. In this connexion it should be remembered that lack of care early in the disease increases the severity and mortality rate.

To sum up, in judging the effect of vaccine in typhoid cases I have tried to be certain of the following essentials (without which results will be fallacious): 1. Proof of infection by B. typhosus in all the cases, including the controls. 2. Accurate selection of these control cases—that is, (*a*) as far as possible the classes of cases and groups of cases compared are of the same degree of severity; (*b*) there is the same state (or lack) of inoculation in the cases compared; (*c*) all the cases occurred in the same season of the year and in the same climate and locality; (*d*) all were of the same sex and of about the same age and previous health; and (*e*) other modes of treatment (nursing, dieting, &c.) were similar.

Clinical grouping of the cases.—The classes referred to, into which the 230 cases were divided, varied according to the apparent condition of the patient on admission or after a day or two of observation, each class of vaccinated cases having a control class of the same size. It should be noted that the final result of the case was not taken into account, but the state of the case before treatment was started. I will briefly explain the method of this classification. A flushed, drowsy patient obviously ill is said to be looking "toxic" (Cases 8, 112, 162, &c.), and this expression is used by all the medical officers in describing their cases. For instance, a patient who has a typical typhoid aspect with a sallow, muddy complexion and malar flush, who is lying inert on his back, mentally fuddled or delirious and looking obviously poisoned, is described as "very toxic," whereas an alert mentally clear man merely looking slightly febrile is described as "quite non-toxic." The severity of the case usually, but by no means always, varies directly with the degree of toxæmia thus evident. In judging the severity the following points were especially considered: (*a*) The rate and type of the pulse; (*b*) the amount of pulmonary involvement; (*c*) the temperature; (*d*) the amount of distension; and (*e*) the day of the disease. The day of disease is counted from the day which appeared by the previous history to be the first day of illness. On these lines the 230 cases were divided into—

Class 1 ...	32	cases,	very severe and very toxic.
,, 2 ...	86	,,	severe and toxic.
,, 3 ...	56	,,	of moderate severity.
,, 4 ...	44	,,	moderately severe, but quite non-toxic.
,, 5 ...	12	,,	mild.

The vaccine and dosage.—The vaccine used (with 4 exceptions) was the stock army vaccine, made up for treatment purposes in the dilution of 250 millions to the c.c. The other 4 cases had a sensitised vaccine. The initial dose, the interval between the doses, and the rate of increase of the dose were all the subject of careful trial. In many of the earlier cases I had the great benefit of Sir William Leishman's advice and guidance. A small initial dose of 80–100 millions was tried in certain cases, but this did not seem sufficiently strong. There were some patients who had received their first inoculation during or immediately before the apparent onset of the disease (Case 164), and who were therefore considered to have had a big dose of vaccine (500 or 1000 millions) early in their attack. Some of these patients did unusually well, and therefore a similar big initial dose was tried in other cases (Case 162). Also these and other cases seemed to support the view that the sooner the vaccine was given the better was its chance of doing good, but later there were some cases of this variety which did badly. At one time we had the impression that it was very important to inject vaccine early, but perhaps this was due to the obvious fact that the sooner any case comes under ordinary treatment (bed, nursing, and dieting) the better chance has that patient of doing well. Eventually a first dose of 200–250 millions was usually given as a routine, and subsequent doses were usually injected at intervals of 2–3 days, rising by about 100–200 millions each time to 500 or 600 millions. The time of day for injection was varied. In nearly all cases I gave my patients their injections between 5 and 7.30 P.M. —i.e., when the temperature was usually rising. The other medical officers gave the injections during the morning when the temperature was down or falling. It was thought that as there is frequently a decided difference in the temperature and state of the patient as observed in the morning and in the evening, the time of day might be important, but the result did not support this view. It seemed both impossible and unwise to keep to any strict rule, and the system of dosage varied much with the individual case. If there was much local reaction or if there appeared to be a marked general reaction there was no increase of dose, or the increase was more gradual. Also if there was no local reaction and apparently no general reaction a bigger dose was often given the next day.

To be certain that a general reaction to the vaccine has occurred at any particular time in the course of a case is most difficult. All the medical officers here, after observing a large number of cases, eventually came to the conclusion that the temperature chart was a fallacious guide to the effect of any particular dose. In this matter I am unable to follow those who have described cases of typhoid in which rises and falls in the temperature were stated with assurance to have been due to the vaccine. Many of the control cases would have been considered good results for vaccine had they received it (Case 23).

Results in the Whole Series.

The total *mortality* in the 230 cases (115 vaccinated, 115 selected controls) was 52 (22·6 per cent.), this being made up by 29 deaths in the vaccinated cases (25 per cent.) and 23 deaths in the unvaccinated (20 per cent.).

The average *length of the primary period of pyrexia* (neglecting fatal cases) was 27·5 days. The average date on which the temperature settled was the twenty-ninth day in the vaccinated cases and the twenty-sixth day in the controls.

The total number of cases having a *relapse* was 22 (9·5 per cent.), and of these 12 occurred among the vaccinated and 10 among the unvaccinated. In this investigation a relapse was taken to mean a rise of temperature lasting several days during which there was some recurrence of the previous

typhoid symptoms and signs. Rises of temperature due only to a complication or sequela are not included.

The total number of patients with *complications or sequelæ* of some kind or another was 111, and of these 58 were among those who had vaccine and 53 among the unvaccinated. The more important of these complications were distributed as follows:—

Total 230 cases.		Vaccinated.	Controls.
Hæmorrhage	30 (13%)	17 (14·7%)	13 (11·2%).
Perforation	7 (3%)	5 (4·3%)	2 (1·7%).
Thrombosis and phlebitis	7 (3%)	4 (3·4%)	3 (2·6%).
Severe post-typhoid debility or prolonged convalescence	33 (14%)	19 (15·7%)	14 (12%).

"Hæmorrhage" does not include the fairly numerous cases in which only streaks of blood or minute quantities were present in the stools. Hæmorrhage from the bowel was the cause of death or the deciding factor in 6 of the fatal vaccinated cases and in 5 of the controls. It was noted that in some of the cases the hæmorrhage started just after a dose of vaccine or recurred after a dose (see Cases 162 and 164). Such cases may have been coincidences, like many other things, good and bad, which occur during vaccine treatment. There is, however, the possibility that after a dose of vaccine greater inflammatory reaction may occur in the ulcerated Peyer's patches, and the increase in the local blood pressure then occurring at these spots may be the decisive cause of the bleeding.

Pulmonary involvement and *meteorism* are not in the above list as, except in the mildest cases, there is always more or less chest trouble and more or less abdominal distension and it has seemed difficult to say at what stage conditions so frequently present become complications and are no longer to be considered part of the usual course of the disease. It seems certain, however, that vaccine has no power to prevent or to produce them, or to diminish them when present except in so far as it may affect the general health of the patient. The presence or absence of these conditions was always carefully noted in attempting to judge the effect of vaccine, and the vaccine rarely seemed to have any good effect in cases with much bronchitis or bronchopneumonia.

Note.—It must be remembered that (*a*) this high death-rate is the rate for a particular set of picked cases; (*b*) that 200 of the cases were uninoculated, that they occurred during the winter months, and many of them under adverse conditions unavoidable at that time (slow evacuation to fever hospitals, &c.); and (*c*) that 177 of them had B. typhosus isolated from the blood stream, and were therefore very definitely infected.

The death-rate for the hospital of the true typhoid cases was 12·4 per cent., being made up of a rate of 16·5 per cent. in the uninoculated and 8·1 per cent. in the inoculated up to November, 1915.

Results in the Uninoculated Cases.

In the 200 uninoculated cases (100 on vaccine and 100 controls) the following are the results:—

The 200 cases.		Vaccine. series.	Controls
Mortality	47	25%	22%
Average length of pyrexia in days	27·5	29·4	26
Cases with relapses	19	10%	9%
Cases with complications or sequelæ	101	51	50

These results require a close analysis to show how the various types of case were affected. The classes will now be dealt with separately. (For Summary see Table I.)

Class 1. Very severe and toxic.—28 cases (14 with vaccine and 14 without).

(*a*) *Among the vaccinated cases* there were 9 deaths (64·2 per cent.) and 5 recoveries. Of the fatal cases, 5 died of toxæmia and cardiac failure with basal congestion and bronchopneumonia in varying degrees 7, 3, 11, 5, and 7 days after

TABLE I.—*200 Uninoculated Cases: Statistics of the Five Classes, with and without Vaccine, and of the total 200.*

—	Class 1.		Class 2.		Class 3.		Class 4.		Class 5.		Percentage or average in		
											Total 200.	100 on vaccine	100 no vaccine.
With (+) or without (0) vaccine	+	0	+	0	+	0	+	0	+	0		+	0

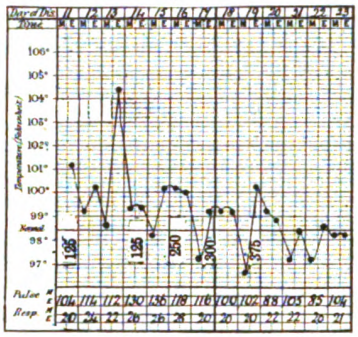
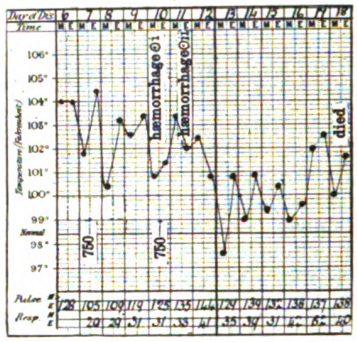
Prolonged convalescence from severe debility and other causes not mentioned	1	2	12	11	3	0	2	0	—	—	15·5	18	13

(1) Was the cause of or was associated with death in 6 vaccinated cases and 5 unvaccinated. (2) By this is meant evanescent rises of temperature which are not relapses and which are not associated with a complication or sequela. (3) Only cases in which there were destructive changes in the larynx are included (sore-throat, &c., not necessarily included). *a*. One death in a case admitted in a dying condition. *b*. The supposed cause of a pulmonary infarct (fatal). *c*. With abscess formation. *d*. Two with abscess and two without. *e*. Ulceration followed by cicatrisation requiring tracheotomy. *f*. Temporary insanity. *g*. Tonsillitis. *h*. Includes 1 case of biliary colic and jaundice. *i*. Includes 1 case of septicæmia and endocarditis (fatal) and 1 case of glomerular nephritis (fatal).

admission respectively. These cases in this order had 2, 1, 2, 3, and 2 injections of vaccine, and I doubt if it had any influence on them at all. Of the other 4 fatal cases, 1 got steadily worse and died of perforation 11 days after admission, and vaccine possibly did harm in this case. Perforation occurred the day after the second dose. Another case became steadily worse, having two severe hæmorrhages after the injection, and died 13 days after admission, and here also vaccine possibly did harm as the case was admitted early in its course and the bleeding occurred on the tenth and eleventh days. (See Case 162.) Another case died of hæmorrhage 36 hours after admission, having arrived in a collapsed condition as a result of severe bleeding during the journey. A small dose of vaccine (100 millions) was given after he had revived, and the hæmorrhage recurred. I do not think vaccine did him harm as no form of treatment could have saved him. In the remaining fatal case the temperature came down steadily after four doses of vaccine, but at the same time the pulse-rate and the delirium were bad, the patient was in a very asthenic condition, and he died 15 days after admission of a rapidly spreading pneumonia.

CHART 1 (Case 112).





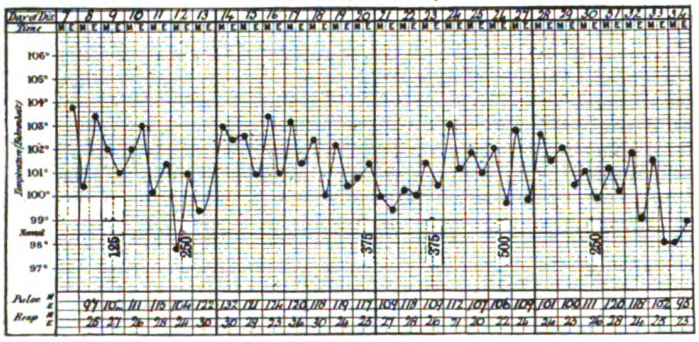


CHART 2 (Case 162).

Of the 5 survivors, in one vaccine certainly appeared to do good. This case is shown, and is one of those in which the temperature is no guide to the effect of vaccine (Case 112). In another the patient did not look as if he were going to pull through during his second week, but he began to get better after the third dose, and finally reached a normal temperature on the twenty-fourth day, which was rather soon considering the severity of the case. I think vaccine may have benefited him. The other 3 cases all ran a severe and long course, and all got rather worse after the first two or three doses of vaccine, and except for the fact that they did survive there is no reason to suppose that vaccine had a good effect, and one had a very tedious convalescence. One of these cases is shown together with a similar control case. (Case 111 and Case 8.) The average length of the primary fever in the 5 surviving cases was 31 days.

CHART 3 (Case 111).

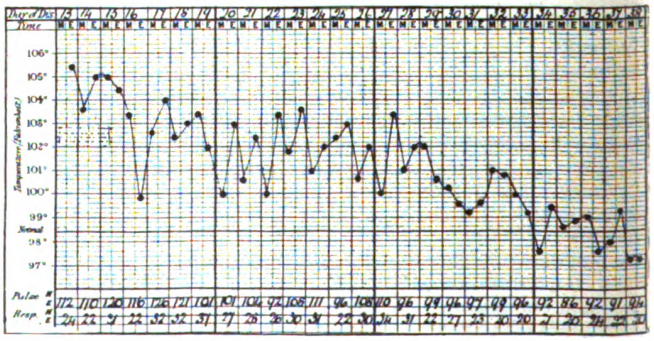
(*b*) *Among the unvaccinated cases* there were 10 deaths (71·4 per cent.) and 4 recoveries. Of the fatal cases 6 died of toxæmia and cardiac failure with broncho-pneumonia 8, 6, 2, 6, 16, and 13 days after admission, living on the average three days longer than the 5 similar vaccine cases. The 4 other deaths were due respectively to (α) hæmorrhage, (β) acute glomerular nephritis, (γ) acute gangrenous decubitus and septicæmia coming on 21 days after admission, and lastly (δ) toxæmia associated with facial erysipelas.

The 4 surviving unvaccinated cases were all critically ill during their course. In the end 2 did very well and had an uninterrupted convalescence, and 1 of these (Case 8) is shown with a similar case on vaccine treatment (Case 111). The average length of the primary fever in the 4 surviving cases was 36 days.

The effect of vaccine in this class may be summed up thus: In 1 case it certainly appeared to do good, and it may have done good in another. In 1 case it did not have a fair chance. In 1 case it appeared to do harm, and it possibly did harm in 2 others. In 4 it certainly did no good, and in the remaining 5 it cannot justly be said to have had an effect one way or the other. I do not think that a conclusion for or against should be drawn from a comparison of the mortality rates as the total number of cases was small, and in 2 of the non-vaccinated cases the cause of death was most unusual.

Charts.

Note.—All the cases shown are uninoculated patients unless otherwise stated. The average rates of pulse and respiration for the whole day are marked. The printed figures denote the dose of vaccine given in millions of bacilli.



CASE 112 (Chart 1.)—On admission eleventh day: Sallow complexion with malar flush, toxic; dry furred tongue; regular pulse; abdomen distended and tender; feeble heart sounds; lungs normal. Fourteenth day: Rapid feeble pulse; bad sallow toxic look and muttering delirium. Twentieth day: Fall of temperature with profuse sweating; pulse now good; patient undistressed and sensible. Steadily improved from this day onwards.

Summary.—A very toxic severe case soon after admission (Class 1). Noticeable for quick improvement in mental symptoms and cardiac weakness. Apparently a good result for vaccine. Note entire absence of pulmonary involvement. Blood culture grew B. typhosus.

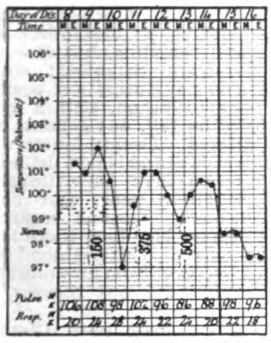
CASE 162 (Chart 2).—On admission sixth day: Flushed, lethargic, inert; typical appearance of acute toxic type with tendency to pseudo-pneumonic variety; small regular pulse; distended soft abdomen; diffuse coarse bronchitis. Blood culture grew B. typhosus. Ninth day: Voice lost; distension marked; bronchitis marked; general condition the same. Fifteenth day: Rapid poor pulse, mouth very dry, very toxic.

Summary.—A typical very severe toxic case (Class 1). Vaccine possibly did harm as patient got steadily more toxic. Pulmonary involvement became worse and he had two severe hæmorrhages in association with the injections.

CHART 4 (Case 8).

CASE 111 (Chart 3).—On admission seventh day: Pinched and flushed and looks ill, drowsy and cannot remember. Pulse regular but soft and dicrotic; tongue has dry brown

fur; abdomen full and moves badly; slight bronchitis. Blood culture grows B. typhosus. Thirteenth day: Toxic and drowsy; tongue still dry; pulse poor; more distended. Twenty-third day: Very drowsy; poor pulse, cardiac weakness the chief danger; more bronchitis. Twenty-ninth day: Poor pulse; slight but steady general improvement. Slow convalescence owing to dilated heart with rapid pulse.



Summary.—Typical severe toxic and prolonged case (Class 1). Did not look like pulling through at one time. Vaccine not thought to have had any definite effect. Note rise in temperature and pulse-rate after second dose. Compare with Case 8.

CASE 8 (Chart 4).—On admission thirteenth day: Flushed, talks incoherently; pulse soft and thready; tongue dry and tremulous; abdomen distended and tender; much bronchitis. Blood culture grows B. typhosus. Eighteenth day: Better; bronchitis seems the chief danger. Twenty-sixth day: More toxic in appearance; stools frequent and undigested; pulse is steady and of better volume. Thirty-third day: No distension; pulse fair; does not look toxic. Slow steady improvement from now onwards.

Summary.—Very severe toxic and prolonged case (Class 1), which has done very well in the end without vaccine. Compare with Case 111.

CASE 0 (Chart A).—On admission eighth day: Looks ill and seems slightly delirious. Pulse of low tension but not dicrotic; abdomen distended and slightly tender; little or no bronchitis; spleen felt and large crop of large spots. Sent into hospital with culture from blood stated to be B. typhosus. Tenth day: Delirious; dry brown toxic tongue. Twelfth day: Improving; not delirious. Sixteenth day: Markedly improved all round; abdomen flaccid.

CHART A (Case 0).

Summary.—"A severe typical toxic case. Considered a good result for vaccine treatment, which markedly affected for the better both temperature and general condition." (Quoted from notes made at time of patient's discharge from hospital.) The culture obtained from blood was subsequently further examined and gave quite definitely all the cultural reactions of the B. paratyphosus A, and also fulfilled the agglutination and absorption tests. It is rather a characteristic of paratyphoid cases to take a sudden turn for the better a few days after admission. The supposed "good result," therefore, was a fallacy.

Class 2. Severe and toxic.—74 cases (37 treated with vaccine and 37 without).

(*a*) *Among the vaccinated cases* there were 13 deaths (35 per cent.) and 24 recoveries. In 6 of the *fatal cases* one is not justified in saying that vaccine affected the result. The causes of death in these 6 cases were as follows: Toxæmia and broncho-pneumonia in 3 cases; cellulitis and terminal septicæmia in 1 case; intestinal obstruction by adhesions resulting from a shut-off and healed perforation in 1 case; and lastly, toxæmia, with, in addition, ulceration of the vocal cords and epiglottis, in 1 case.

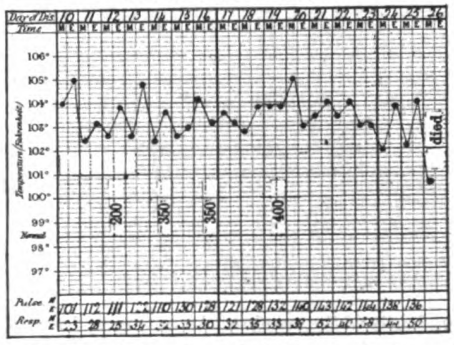
In 2 of the fatal cases vaccine certainly appeared to have a bad effect. In one of these (Case 159) the patient became worse in every way after four injections, and died on the seventeenth day after admission. In the other of these vaccine was given on the thirtieth day to see if it would stimulate the patient to finish off a long course, and this single dose was followed by fatal hæmorrhage (Case 164).

In the 5 remaining fatal cases there is a strong suspicion that the vaccine was harmful. In one the vaccine was given a good chance, as he had seven injections, but he slowly and steadily became worse, and finally perforated 22 days after admission. The second, who had five injections, died of toxæmia and pulmonary congestion 14 days after admission. The third died in three days of hæmorrhage commencing 36 hours after an injection of 250 millions. In the fourth case death occurred from toxæmia and broncho-pneumonia, but he had some hæmorrhage following on two doses of vaccine. The fifth of these cases died also of toxæmia and lung involvement, but he had become more delirious and altogether worse after two injections.

Of the 24 *recoveries*, 2 certainly appeared to have been benefited by the vaccine—that is to say, not only did they do well and quickly, but much more so than might have been expected considering their severe condition on admission (Case 117).

Another case appeared to have done unusually well, but had a severe relapse, and therefore cannot be considered a good result for vaccine. In 1, vaccine was only given in a relapse, and, as this was quite short, it may have done good in this way.

In four other cases it may possibly have been beneficial, as they all did fairly well and made a good convalescence. Eight of the cases ran a severe and rather long course, but this was no more than might have been expected and one cannot say that vaccine affected them one way or the other (Case 114 and Case 177). In 1 case the vaccine was stopped after two injections as the patient was doing badly owing to severe involvement of the lungs.



In 6 of the cases vaccine appeared to do harm, as although it was thoroughly tried, all these cases had long courses (two of over 80 days) which were associated with great weakness, wasting, and other complications. The average day of the disease on which the temperature first settled was the thirty-sixth, whereas in the controls it was the twenty-seventh day.

(*b*) In the *non-vaccinated* cases there were 10 deaths (27 per cent.) and 27 recoveries. Six of the fatal cases died of toxæmia and broncho-pneumonia, with a course similar to that of the vaccinated cases of this type. One of the 6 had a severe and one a slight hæmorrhage. Two cases died of perforation. In one of these the perforation did not occur till about the seventh week of the disease, and the other one had a hæmorrhage preceding the perforation. One case which had suppurating parotitis died of a confluent broncho-pneumonia. The remaining fatal case had thrombosis of the left femoral and external iliac vein and finally died as the result of pulmonary infarct and pleurisy.

Of the 27 recoveries, 10 ran the usual course of such cases, nearly all of these making a good convalescence. Two cases did remarkably well considering their apparent severity on admission. These cases are shown, as had they been given vaccine they would have appeared good results for this treatment (Cases 32 and 23). Two cases ran a course worse than the average, one being very prolonged and complicated by hæmorrhage, parotitis, and pyelitis, and the other was prolonged for six weeks but without complications. Of the remainder, 6 patients did rather better than usual and had no complications or sequelæ, whereas 8 others did rather worse than usual and all had one or more complications.

***Summary of this class.*—I wish to draw particular attention to this class as a test of vaccine, because, whereas in Class 1 the prognosis is bad, and in Classes 3, 4, and 5 fair to very good, it is in Class 2 that the prognosis is doubtful. It was hoped that in this class vaccine treatment might be found to turn the balance. It will be seen from the above analysis that this is not so. The mortality-rate is not lowered, neither is the incidence of relapses or complications lessened by this stock vaccine. Also the average cases which did well with vaccine ran a course very much the same as the average case which did well without it, and the cases which did exceptionally well in either group are balanced by such cases in the other. Finally, the average length of the primary period of pyrexia in the vaccine treated cases was longer by nine days than in those cases which had received no vaccine.**

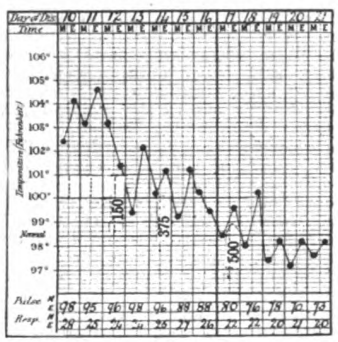
CHART 5 (Case 159).

CASE 159 (Chart 5).—On admission tenth day: Looks toxic, but is quite sensible. Pulse soft and dicrotic; abdomen slightly distended and generally tender; bronchitis both bases. Blood culture = B. typhosus. Thirteenth day: Delirious; bases congested and broncho-pneumonia of influenzal type. Fifteenth day: Rigor followed vaccine. General condition is not so good, he is more delirious, and

abdomen is more distended. Twentieth day: Vaccine given at 7 P.M. last night. At 3 A.M. this morning much worse, temperature rose to 105° F., and pulse to 150. Is now very toxic with widely dilated pupils. Patient continued very toxic and finally died of exhaustion.

Summary.—A severe case (Class 2) which got decidedly more toxic while on vaccine. Vaccine certainly appeared to do harm, as patient was worse after each individual dose.

CHART 6 (Case 117).



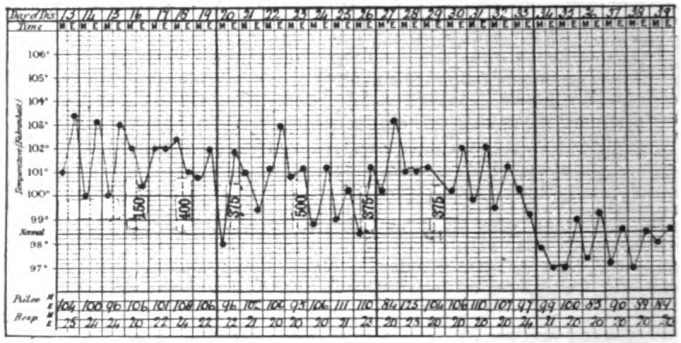


CHART 7 (Case 114).

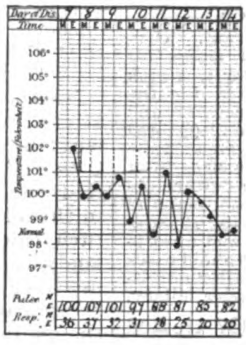
CASE 117 (Chart 6).—On admission tenth day: Looks rather toxic, but mental condition is clear. Pulse is soft but not dicrotic; abdomen distended and slightly tender; heart sounds good; much big tube bronchitis. Thirteenth day: Toxic and delirious and trying to get out of bed. Blood culture = B. typhosus. Fifteenth day: Decidedly better; tongue moistening; profuse crop of spots all over body. Continued to make rapid progress.

Summary.—A rather severe and decidedly toxic case (Class 2) which has done remarkably well and rapidly and is apparently a good result for vaccine, but the absence of severe pulmonary involvement and the comparatively slow pulse throughout suggested a fairly good prognosis.

CASE 114 (Chart 7).—On admission thirteenth day: Mentally clear when roused. Small regular pulse; "beefy" tongue; abdomen not distended; spots are very numerous; no bronchitis. Blood culture = B. typhosus. Eighteenth day: Rapid, poor, irregular pulse; looks toxic. Twenty-first day: Pulse better; shows all-round improvement (? post or propter vaccine). Twenty-fifth day: General improvement continues, but temperature chart not affected. Thirtieth day: Continues doing well; quite undistressed; abdomen hollowed; temperature as before. Thirty-eighth day: Doing well, but looks pinched and is very wasted.

Summary.—A typical severe case (Class 2), marked by myocardial weakness. Final result good. There does not appear to be much evidence, however, that vaccine did any good. Case was prolonged and temperature was irregular

CHART 8 (Case 32).



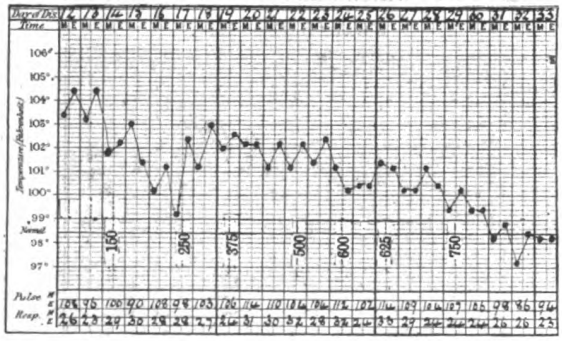


CHART 9 (Case 177).

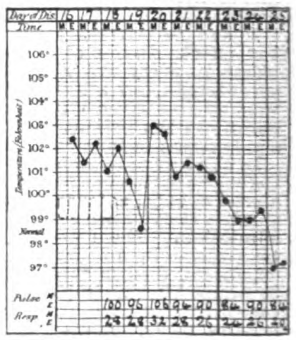
independently of the vaccine. An example of several similar cases.

CASE 32 (Chart 8).—On admission seventh day: Toxic, flushed, incoherent, and later had muttering delirium. Regular, good pulse, not dicrotic; tongue is dry, with brown fur; abdomen full; respirations rapid, but no moist sounds in chest. Blood culture not done; Widal reaction = negative. Eighth day: Restless, delirious, and noisy; flushed and toxic. Tenth day: Remarkable change; no delirium; does not look toxic and is at his ease. Widal reaction = positive to B. typhosus. Patient went straight ahead to make an uninterrupted recovery.

Summary.—Appeared a typical severe and very toxic case (Class 2). Made a remarkably good and rapid recovery. If vaccine had been given would undoubtedly have been thought a good result for this treatment, and the case, therefore, should be compared with No. 117 (Chart 6).



CASE 177 (Chart 9).—On admission fourteenth day: Flushed, toxic, and delirious, picking at bedclothes, and very talkative. Pulse is full and bounding, but dicrotic; tongue dry, brown fur; abdomen distended; coarse bronchitis. Blood culture negative; agglutination positive to B. typhosus. Eighteenth day: Flushed, still a little delirious; temperature fell, but general condition was not altered. Twenty-fourth day: Quieter the last few days and is now definitely improving. Thirtieth day: Slow improvement; mental condition poor, and he is frequently incontinent. Vaccine seems to have no effect; despite big dose there is no local or general reaction. Thirty-second day: Slow general improvement from now onwards, but mental condition did not recover for another ten days.

Summary.—A severe toxic case (Class 2) with mental weakness, pyrexia prolonged to end of fifth week. Ultimate result good. Had seven injections of vaccine which certainly did not shorten case, and it is doubtful whether vaccine had effect. Case is shown as an example of many similar cases which eventually did well but in which vaccine appeared to have no definite effect.

CASE 23 (Chart 10).—On admission eighteenth day: Flushed, looks toxic, laboured breathing; pulse of big volume but soft; abdomen not distended; no moist sounds, although slightly cyanosed and breathing deeply. Twenty-first day: Much better all round, and has lost his toxic look. Went ahead rapidly after this. Blood culture before admission reported as B. typhosus. Blood culture was negative here, but agglutination reactions strong with B. typhosus.

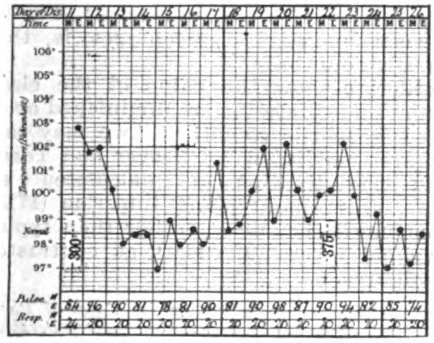
Summary.—Typical toxic and apparently severe case (Class 2) on admission, which rapidly improved in an unexpected manner without vaccine and which made a rapid convalescence. Case is shown as an example of several which, if they had received vaccine, might have been thought good results.

CHART 10 (Case 23).

Classes 3 and 4. Moderately severe and slightly toxic or not toxic.—88 cases (44 treated with vaccine and 44 without). These two classes of case are considered together, as they form degrees of the same kind of case in which the prognosis varies from "good" to "very good." It is especially in this class of case that a good effect of vaccine is difficult to judge, as all are likely to do well, and vaccine is therefore liable to get undeserved credit

unless the unvaccinated controls are considered. The statistics of the control cases must be carefully examined (see Table I.), and it will then be seen that the effect of vaccine, in so far as it has a good influence, is practically negligible.

(*a*) In 5 of the *vaccinated cases* there did certainly appear to be an effect on the case as a whole, and in 1 each injection seemed to have a marked effect (Case 124). But cases of a similar nature may occur without vaccine treatment. In 10 other cases vaccine may have shortened the fever, and therefore may have done good in these.



In 1 fatal case it certainly appeared to do harm, as this case was neither very severe nor toxic, and yet the patient got progressively worse while on vaccine and died of toxæmia and cardiac failure (Case 140). In the other fatal case which had vaccine death was due to sudden hæmorrhage on the seventeenth day of disease following on a dose of vaccine. There was, however, just such a case of fatal hæmorrhage occurring on the eighteenth day of disease in one of the controls. Vaccine may have been the decisive factor, but the hæmorrhage may thus have been a coincidence.

In 5 other cases the course was long or otherwise worse than the average, and vaccine may possibly have done harm to these. In the remaining 22 cases the patients did well, but just as might have been expected, and I do not think vaccine affected them either way.

(*b*) *In the 44 unvaccinated cases* there were also 2 deaths. One already referred to died of hæmorrhage, and the other also had hæmorrhage, but died with increasing severity and toxæmia.

The great majority of the cases ran the course that was expected. The average length of fever in the vaccinated and unvaccinated cases of these classes was about the same and is shown together with the incidence of complications and sequelæ in Table I.

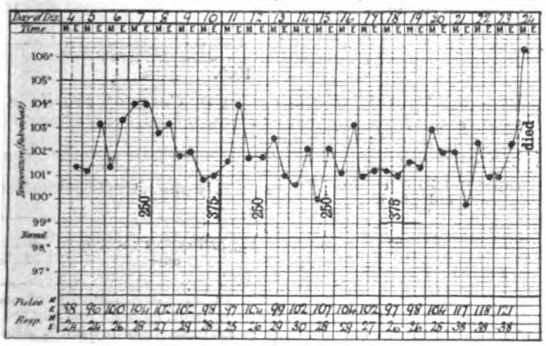


CHART 11 (Case 124).

CASE 124 (Chart 11).—On admission eleventh day: Sallow, with slight malar flush; lethargic, but clear mentally when roused. Regular, good volume, soft dicrotic pulse; normal abdomen and no moist sounds in chest. Blood culture negative; stool of thirteenth day grew B. typhosus.

Summary.—A case which looked moderately severe (Class 4), but with an excellent prognosis. Did very rapidly but had a relapse. Case is shown as one of the few in which each individual dose of vaccine appeared to have a marked effect both on temperature and general condition.

CHART 12 (Case 140).

CASE 140 (Chart 12).—On admission seventh day: Pale and looks ill; lethargic, but quite clear when roused; big volume, but very soft and dicrotic pulse; abdomen is not distended; no moist sounds heard in chest. Blood culture = B. typhosus. Fourteenth day: For the first few days was bright in the mornings and could read the paper. Is now getting a little more toxic; wanders at night; abdomen now tumid; pulse good and rarely above 100. Eighteenth day: Continues as above. Sleeping draught required at night. Tongue now quite dry and typical; pulse soft and dicrotic. Is now rather a severe case. Twentieth day: Very restless; is distended and has diarrhœa; heart is getting dilated. Twenty-third day: Heart shows cantering rhythm. Tubular breathing left lower lobe, but rapid respiration is mostly toxic. Seems to be going downhill with cardiac weakness associated with a steadily increasing and now severe toxæmia. Vaccine quite useless (? has increased toxæmia).

Summary.—A typical slightly toxic and moderately severe case (Class 3)—*vide* pulse-rate, respiration-rate, absence of distension, &c., on admission. Patient had the appearance of one likely to do well, and vaccine therefore undoubtedly appeared to do harm.

Class 5. Very mild.—10 cases (5 treated with and 5 without vaccine).

One death occurred in this class in a man who had a severe relapse (?) and prolonged fever, after what appeared to be a very mild preliminary attack. It was only when in this acute stage that he had vaccine and the death is therefore in brackets in the comparative tables. Two vaccinated cases ran an unusually long course, and it should be noted that the average length of fever in the vaccine-treated cases was much longer than in those who did not receive it. As the numbers are small one can only say that in this class the vaccine did not appear to have any good effect.

The Inoculated Cases.

There are 30 of these, half being treated with vaccine. They had all been inoculated once or twice during the nine months preceding their illness. B. typhosus was isolated from each. As the number in each series is small I do not think that much can be deduced from the statistics. The more important facts are set out in Table II.

TABLE II.

—	Class 1.		Class 2.		Class 3.		Class 4.		Class 5.	
With (+) or without (0) vaccine	+	0	+	0	+	0	+	0	+	0
Number of cases in class...	2	2	6	6	4	4	2	2	1	1
*Mortality	2	0	2	1	—	—	—	—	—	—
Average length of fever ...	—	25·5	35	27	25	27	25	28	21	23
Hæmorrhage	1	—	1	1	—	1	—	—	—	—
Perforation	1	—	1	—	—	—	—	—	—	—
Relapse...	1	—	—	—	1	—	—	—	—	—
Prolonged convalescence	—	1	—	—	1	—	—	—	—	—
Thrombosis	—	—	—	—	1	—	—	—	—	—

It will be seen that in the above 15 cases vaccine had no good effect on the mortality or on the incidence of complications. I do not think that one can say that it definitely had a bad effect on the cases as a whole as the numbers are small. One outstanding fact, however, is that the average length of fever amongst the vaccinated cases of Class 2 (the largest class) was much longer than that of those in this class who had no vaccine.

* One of the cases of Class 1 which died was admitted in a critical condition with a subnormal temperature. He had one injection, after which the temperature steadily rose and he died 36 hours afterwards. In the other fatal case of this class the temperature took six weeks to reach normal; the patient then had a relapse, during which he died of perforation of an old ulcer. Of the 2 fatal vaccinated cases of Class 2, one died of perforation after three injections and the other died of a confluent broncho-pneumonia, being then in a very asthenic state with a subnormal temperature. There was no case among the series receiving vaccine which did markedly better than any of the control cases.

In none of the 4 cases which were given the *serum-treated vaccine* is there any reason to suppose that their course was definitely affected. One of the cases died of toxæmia. It was a severe prolonged case, and the serum-treated vaccine was given late in the disease to see if it could stimulate the patient to further efforts, but without effect.

Summary and Conclusions.

In the total vaccinated cases there were 29 in which it appeared that vaccine had a definite good influence. Of these, 20 belonged to Classes 3 and 4

—i.e., to those classes in which the prognosis is good. In other words, "good results" are more often obtained where good results can be expected by ordinary methods of treatment alone. On the other hand, the mortality rate and the average length of fever in these classes were slightly worse among the cases who had vaccine.

Among the cases belonging to Classes 1 and 2 in which the vaccine appeared to do good none had severe lung involvement. Those cases which had much bronchitis or broncho-pneumonia (the average severe case) ran the severe course which is usual and vaccine appeared to be of no avail. To say that, if the average severity of the cases treated had been less the vaccine would have had better results, is merely to say, I think, that the cases would then have done better anyhow.

From all this it would appear (*a*) that it is in just those cases in which the physician so much requires help that vaccine is disappointing; (*b*) that vaccine neither shortens the fever nor reduces the number of complications in even that class of case which is likely to do well; and (*c*) that there is a decided suspicion that vaccine increases the incidence of hæmorrhage.

Therefore the conclusion is that the use of a stock vaccine in typhoid cannot be recommended as a routine treatment.

I should add that these conclusions are largely contrary to the impressions which I received during the treatment of the earlier cases. I had not then seen a sufficient number of similar cases which did well without vaccine, and being rather biassed in its favour I gave undeserved credit to this treatment.

FURTHER REMARKS ON AGGLUTINATION TESTS IN INOCULATED PERSONS,

AND THE INFLUENCE OF FEBRILE CONDITIONS ON INOCULATION AGGLUTININS.[1]

BY GEORGES DREYER, M.A. OXON., M.D. COPENHAGEN,
MAJOR, R.A.M.C.; PROFESSOR OF PATHOLOGY, UNIVERSITY OF OXFORD; FELLOW OF LINCOLN COLLEGE;

ALEX. G. GIBSON, M.D. OXON., F.R.C.P. LOND.,
CAPTAIN, R.A.M.C.; LECTURER IN MORBID ANATOMY, UNIVERSITY OF OXFORD; AND

E. W. AINLEY WALKER, M.A., M.D. OXON.,
LIEUTENANT, OXFORD UNIVERSITY O.T.C.; LECTURER IN PATHOLOGY, UNIVERSITY OF OXFORD; FELLOW AND TUTOR OF UNIVERSITY COLLEGE.

(*From the Department of Pathology, University of Oxford.*)

IN the course of the discussion on Paratyphoid Fever at the Royal Society of Medicine on Nov. 25th, 1915, Captain H. L. Tidy[2] made known certain conclusions which he had arrived at regarding the value of agglutination tests in typhoid and paratyphoid fevers and other febrile conditions. These conclusions were so completely divergent from previously established results that Dreyer and Torrens[3] at once briefly summarised in a letter to THE LANCET the mass of evidence then in their possession which showed the complete untenability of Tidy's views. Shortly afterwards Ainley Walker[4] dealt with the same contentions by showing that this marked discrepancy in results seemed only to be explicable by a recognition of the gross character of the fallacies inherent in the method used by Tidy.

In apparent ignorance of the emphatic contradictions of his statements regarding the influence of febrile conditions on inoculation agglutinins offered in these communications, Tidy repeated and amplified his conclusions in a recent issue of this journal[5] in a preliminary note on a report to the Medical Research Committee.

Unfortunately the matter cannot be allowed to rest here, for Tidy's conclusions would, if accepted, have a most disastrous effect upon diagnosis, and upon our estimate of the protective value of inoculation, since the vast majority of febrile affections occurring in persons inoculated within the preceding year would then necessarily be diagnosed as typhoid fever on the results of properly conducted agglutination tests. Fortunately, however, they can readily be shown to be entirely fallacious. Tidy's contentions are as follows:—

1. Inoculation agglutinins are diminished or entirely removed by febrile conditions. It is possible that they are converted into agglutinoids.
2. In certain cases they may return, but usually do not do so.
3. A positive agglutination reaction to B. typhosus after the fifth day of pyrexia has the same value in an inoculated as in an uninoculated person.
4. Immunity conferred by inoculation may be affected at the same time as the inoculation agglutinins.

The actual number of observations on which these conclusions are based cannot be ascertained from the note in question, beyond the fact that the material included only 14 cases of paratyphoid B fever, and 9 cases "of septic origin." The value of the results quoted in percentages is, therefore, necessarily doubtful.

In order to show the value of the claim that "inoculation agglutinins are diminished or entirely removed by febrile conditions," we may take first the figures published by Dreyer and Torrens for typhoid agglutination in inoculated subjects suffering from paratyphoid infection (171 cases), or from febrile conditions other than typhoid and paratyphoid fevers (97 cases), as contrasted with Tidy's figures.

TABLE I.—*Typhoid Agglutination in Cases of Paratyphoid Fever occurring in Typhoid-inoculated Persons.*

[4] THE LANCET, 1916, i., 17.
[5] THE LANCET, 1916, i., 241.

Hitherto unpublished observations made in the Department of Pathology at Oxford by Dr. A. D. Gardner, Mr. Wilburt C. Davison, and ourselves give the same result as those published by Dreyer and Torrens. The figures are given in Table III.; they comprise 108 cases of febrile affections other than typhoid fever, in persons who had been inoculated against typhoid within the preceding 12 months. Of these cases 42 were cases of paratyphoid A fever, 33 were cases of paratyphoid B fever, and 33 were cases of "other pyrexial conditions" of a continued character.

To facilitate the survey of these results the agglutination titre is expressed not only in standard units, but also in the highest dilution in which agglutination occurred. The cases are arranged in order according to the number of standard agglutinin units in the serum. Five different standard agglutinable cultures were in use during the course of these investigations. Their respective reduction factors (i.e., relative sensitiveness to agglutination) were 4·0, 4·3, 4·7, 5·4, and 6·3. Accordingly, in order to arrive at a true comparison of agglutination titre, attention must be directed to the number of standard agglutinin units per c.c. of serum, which alone affords a true measure of the agglutinating power of any given serum. The importance of thus expressing results in standard agglutinin units is clearly seen from Table III., since with different standard agglutinable cultures agglutination in the same serum dilution does not necessarily imply the presence of the same number of standard agglutinin units in the serum. For owing to the different agglutinability of different cultures each standard agglutinable culture has its own particular reduction factor for calculating the number of standard agglutinin units in any given serum tested. The standard agglutinin unit is that amount of agglutinating serum which, when made up to 1 c.c. volume with normal saline solution, causes standard agglutination on being mixed with 1·5 c.c. of a particular standard agglutinable culture and maintained at 55° C. for two hours in a water bath followed by 15 to 30 minutes at the room temperature. Standard agglutination is the highest dilution in which a given serum causes marked agglutination (without sedimentation) visible to the naked eye. It follows from what has just been said that if standard agglutination occurs in a serum dilution of 1 in 1000, say, then 1000 divided by the reduction factor for the particular standard agglutinable culture employed gives the number of standard agglutinin units per c.c. of the serum.

From the extensive mass of evidence presented in Tables I. to III. it is obvious: 1. That the febrile condition associated with paratyphoid fever does *not* cause disappearance of typhoid agglutinins from the blood of persons inoculated against typhoid. 2. That "other febrile conditions" also, in so far as they have hitherto presented themselves, do *not* cause disappearance of typhoid agglutinins from the blood of inoculated persons. 3. That the statement that "a positive agglutination reaction to B. typhosus after the fifth day of pyrexia has the same value in an inoculated as in an uninoculated person" is entirely erroneous. Its acceptance would lead to such deplorable results in diagnosis that we feel compelled to repeat its categorical denial. For if Tidy's novel view were to be seriously applied in sero-diagnosis the great majority of persons inoculated within a year or so, who suffered from five days' pyrexia, would necessarily be returned as cases of typhoid infection when examined by a reliable agglutination technique.

On examining the new material presented in Table III. rather more closely it will be seen that in *only two* cases does the agglutination titre of the serum fall below 1 in 25. which represents in these cases less than 5 standard agglutinin units per c.c. of serum. But it has been found that the serum of normal non-inoculated persons who have not had typhoid fever only very exceptionally exhibits the presence of as much as 4 standard agglutinin units.[6] It follows that in no less than 106 out of the 108 febrile cases (i.e., 98 per cent.) the agglutinin titre is greater than can be expected to be found in normal non-inoculated individuals. Only in 2 cases (1·9 per cent.) does it fall as low as in the average normal non-inoculated person. And this percentage is not greater than has been found among a similar number of inoculated persons examined at similar intervals after their inoculation, who remained in normal health at the time of examination.

Of 42 cases of paratyphoid A fever recorded in Table III. no case exhibits an agglutinin titre of less than 6 units, which corresponded to agglutination in a dilution of 1 in 50. In the case of paratyphoid B fever the table shows again that of 33 cases no case exhibits an agglutinin titre of less than 6 units.

There are, however, other features of interest to be noted in the table. Thus, so far from paratyphoid fever diminishing the titre of typhoid agglutinins in the serum of inoculated persons, paratyphoid B fever commonly causes a rise in the typhoid agglutinin titre which is frequently of very considerable extent. In the case of paratyphoid A fever both the frequency with which this rise occurs and its extent are usually much less evident. Attention has already been drawn to these points in the Directions for the Use of Standard Agglutinable Cultures which, since the middle of July, 1915, have been issued from this Department on behalf of the Medical Research Committee along with every issue of the Standard Agglutinable Cultures themselves in the following terms:—

In the case of inoculated persons the diagnosis of active typhoid (or paratyphoid) infection will require two or more successive examinations of the serum.

(*a*) If the individual is suffering from active *typhoid* infection his titre of typhoid agglutination will exhibit the usual rise and subsequent regular fall seen in non-inoculated subjects, but starting from and returning towards the higher base line of inoculated persons.

(*b*) If the individual is suffering from active *paratyphoid* infection one of three things may occur as regards his *typhoid* agglutination titre—namely: (1) No appreciable change may occur in the titre of typhoid agglutination; (2) a relatively slight rise may occur, followed by a fall towards the former level; (3) a marked rise may occur synchronous with the rise in paratyphoid agglutination titre, and subsequently followed by the usual fall towards the former level. Meanwhile the titre of *paratyphoid* agglutination runs the normal course of rapid rise to a maximum (usually exceeding the maximum typhoid titre) followed by a fall, at first rapid and then slower as already described for typhoid subjects, and falling *below* the persistent base line of typhoid agglutination of inoculated persons.

In the present series of observations it will be seen that if a serum titre of 25 standard agglutinin units is chosen for purposes of comparison it is found that in the case of paratyphoid B fever (Table III., B) 27 patients out of 33—i.e., 81·9 per cent.—exhibited a titre of more than this number of units, while in the case of paratyphoid A fever (Table III., A) only 24 patients out of 42—i.e., 57·1 per cent.—had a titre exceeding 25 units, and in the case of "other febrile conditions" (Table III., C) only 18 patients out of 33—i.e., 54·5 per cent.—also had a titre exceeding 25 units.

[6] Similar statements hold with regard to paratyphoid agglutinins.

Thus it is obvious that the paratyphoid B cases show on an average a very much higher titre of typhoid agglutination than either of the other series. But there is also an indication that the paratyphoid A cases present a higher titre than the cases of "other febrile conditions." At the same time there is, as already remarked, no indication whatever that these other febrile conditions exhibit a lower titre than is met with in typhoid-inoculated healthy individuals examined at similar intervals after their protective inoculation.

As the results already recorded by Dreyer and Torrens and the new material here presented are entirely at variance with the assertions made by Tidy, we are compelled to conclude that his statement that of the two main techniques with regard to agglutination, microscopic and macroscopic, "they are both reliable, and for diagnostic purposes no further elaboration is necessary beyond the ordinary well-recognised precautions described in text-books," is not borne out by the facts. Tidy states that he has used the microscopic method throughout. Its fallacies have for years been abundantly emphasised in previous communications by the present writers and others. Now that the triple inoculation with mixed vaccine (typhoid, paratyphoid A, and paratyphoid B) has replaced the simple typhoid inoculation, it will be imperative to use methods that give accurate quantitative results. Otherwise the value of agglutination tests in the diagnosis of typhoid and paratyphoid fevers will become negligible. On the other hand, the method of using standard agglutinable cultures has been shown to give accurate and entirely comparable results in agglutination tests whether employed in purely scientific investigations or in the practical diagnosis of disease.

A NEW APPARATUS FOR THE ISOLATION AND CULTIVATION OF ANAEROBIC MICRO-ORGANISMS.

BY JAMES McINTOSH, M.D. ABERD.,
LATE GROCERS' RESEARCH SCHOLAR, ETC.;
AND
PAUL FILDES, M.B., B.C. CANTAB.,
ASSISTANT BACTERIOLOGIST TO THE LONDON HOSPITAL.
(*From the Bacteriological Laboratory of the London Hospital*—Professor WILLIAM BULLOCH, F.R.S.)

As is well known, the methods at present in use for the isolation and cultivation of anaerobic bacteria are in many ways unsatisfactory, and pure cultures of these organisms are so difficult to obtain that they are rarely attempted in ordinary bacteriological work. Indeed, the output of work upon this class of bacteria is relatively so small that some doubt is justifiable as to the correctness of some of the deductions even of the classical investigators.

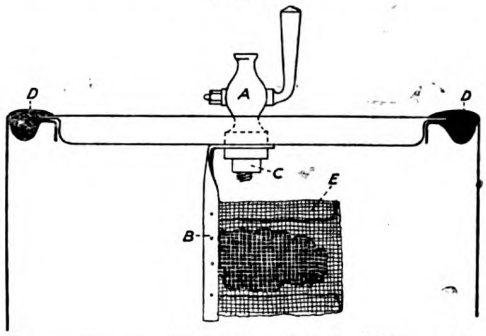
It would appear that the difference between a successful and an unsuccessful growth depends upon the removal of the last traces of oxygen from the environment of the bacterium. Many methods have been devised to achieve this end, but their very multiplicity indicates a lack of means. Bacteria may be protected from the effects of oxygen by any of the following methods:—

1. By covering the surface of a liquid or solid medium with a substance impermeable to air, such as a layer of paraffin or a sheet of mica. The objection here is that oils and paraffin are not entirely impervious, and, further, any oxygen remaining in the medium is not removed.

2. The dissolved oxygen may be driven off by heat if the medium is not coagulable, or a reducing substance, such as glucose or sodium sulphide, may be added to the medium itself. The deep glucose-agar stab is a combination of methods 1 and 2. Under the same category comes the method of Theobald Smith and Tarozzi of adding a fragment of living tissue to the medium, which also has the effect of removing the oxygen. The objection to such methods is that surface growths are impracticable, and the medium requires to be more or less freshly prepared to give the best results.

3. One of the methods most practised is the cultivation in an atmosphere from which the oxygen has been removed by chemical means. An alkaline solution of pyrogallic acid is commonly used for this purpose, as in the well-known apparatus of Buchner and Bulloch. However, the affinity of such substances for oxygen is not sufficiently great to remove the gas totally from an atmosphere.

4. Many methods have been devised for the removal of oxygen by mechanical means, as by displacement with another gas or by the vacuum pump, or by a combination of the two, without, however, achieving decisive results.



We had tried many of these methods without success, when we noticed that Laidlaw had suggested the use of platinised charcoal and colloidal platinum to remove the oxygen from anaerobic cultures, although Pfuhl had previously made use of the catalytic properties of spongy platinum to obtain anaerobic cultures in broth tubes exposed to the air. Our results with this technique were so promising that we determined to work out the method in greater detail, and have succeeded in producing an apparatus by which isolated colonies of anaerobes may be obtained upon the surface of ordinary laboratory media with great facility.

Our method consists briefly in enclosing the culture medium in an airtight vessel which has suspended in it a piece of asbestos wool impregnated with palladium black.[1] The vessel is then attached to a hydrogen generator and hydrogen is allowed to pass in, when it will be occluded by the palladium and combined with any oxygen present. A negative pressure thus develops inside the vessel and hydrogen will pass in until no oxygen remains. The apparatus is then detached from the generator, but the action will still continue and any traces of oxygen which diffuse from the medium itself will be rapidly removed. Thus a more or less complete vacuum towards oxygen is obtained.

The making of the anaerobic apparatus.[2]—A tin with a lever-off lid such as is used for paint is selected. It should measure 7 inches high by 5 inches broad. A small hole is drilled in the centre of the lid, and into this is fitted a small stopcock (A), such as is used for model steam-engines, the joint being made gas-tight with a little solder. Over the thread of the tap on the under side of the lid a small brass bracket (B), as shown in the diagram (Fig. 1), is fitted and secured by screwing up the collar (C) of the tap. The gutter round the top of the tin is next filled with plasticine (D); the pot, after having been tested for tightness, is then ready for use. The gas-tightness of the tin can be readily tested by pouring a few drops of ether inside. The lid is forced tightly into position and a little plasticine turned over the edge of the lid. The tap being shut, the whole tin is placed under hot water and any escape of ether vapour is immediately detected.

The palladium capsule (E) consists of a wire gauze envelope containing 0·25 grm. of asbestos-wool impregnated with palladium black. The palladium asbestos (about 40 per cent.) is made by weighing out 0·25 grm. of asbestos-wool, placing it in a small evaporating dish, and adding 1·5 c.c. of a 10 per cent. solution of palladium chloride. The wool is then moulded into a flat mass about 1 inch square and the dish gently heated until the wool is dry. The palladium chloride is somewhat difficult to dissolve, but the addition of a little concentrated hydrochloric acid will overcome the difficulty. The palladium chloride is then reduced by heating the impregnated wool first in a smoky gas-flame until it is coated with a layer of carbon, and then in the blowpipe. The palladium asbestos should now be able to

FIG. 1.

light a jet of hydrogen which is made to impinge on it. A piece of fine brass wire gauze of suitable size is then folded over the asbestos and the edges doubled over so as to form a complete capsule. The capsule is then clipped by one edge into the brass bracket in a vertical position under the orifice of the tap. Before use the inside of the tin and the under side of the lid should be varnished to prevent rusting, and when dry the bottom of the tin is protected with cotton-wool.

Method of use.—1. Place culture tubes inside the pot. 2. With a rag dipped into spirit spread the plasticine towards the periphery of the top of the tin. 3. Heat the capsule in the Bunsen flame. 4. Immediately force on the lid and push on to the open tap the rubber tubing from the hydrogen generator. The gas need not be purified in any way and commercial chemicals may be used in its preparation. 5. Turn on the gas. 6. After a minute or two close the tap, detach the rubber tubing, and with the moistened rag spread the plasticine from the periphery of the top inwards over the edge of the lid. 7. Again pass in the hydrogen until the increasing pressure stops the generation or the tin is absolutely cold. This takes about 15–20 minutes. 8. When the pot is to be used for gelatine media the temperature inside must be reduced by enclosing a quantity of freezing mixture (salt and ice).

Application of the method to flasks and large tubes.—We have used the same principle in the growth of anaerobes in flasks of broth or in test-tubes too large to get into the pot. In these cases a soft rubber stopper takes the place of the lid of the tin, as shown in Fig. 2, or the capsule may be attached by pins, heated and thrust into the stopper. When using this method it is essential to varnish the whole of the stopper and joints with thin gold size to ensure a gas-tight fitting. The gold size is easily scraped off later with a knife.

FIG. 2.

Anaerobic apparatus consisting of flask with soft rubber stopper. Lettering as in Fig. 1.

Application of the method to plate cultures.—Petri dishes may be enclosed in the pot in place of tubes, but it is desirable to use a small dish which can be accommodated in the standard pot. A larger pot requires a very careful adjustment of the quantity of palladium to the volume of the tin.

With earlier models of the apparatus we incorporated an indicator which showed the degree of anaerobism obtained within. The vessel was then made of glass, and a sterile tube of broth containing methylene blue was placed inside and the degree of bleaching observed. With the present apparatus this indicator is not visible from without, and we rely more upon the presence of a positive pressure, as measured with the hydrogen generator, as an indication of satisfactory conditions within. The only way in which the apparatus can fail is through a slight leak in the tap, and every method to avoid this should be adopted. The tap should be kept well greased and covered with an indiarubber

[1] Platinum may be used instead, but as the reaction is less intense a longer time is required to produce anaerobic conditions.

[2] Messrs. Baird and Tatlock, of 14, Cross-street, London, E.C., are prepared to supply the above anaerobic apparatus.

cap. If a tin is put away with an unsatisfactory tap, especially in the incubator, the cultures may readily be killed or may become grossly contaminated with moulds. When the anaerobic state is maintained satisfactorily moulds never grow inside the vessel.

Practical results obtained with the apparatus.—We have now had our apparatus in use for a number of months and we are able to obtain constantly satisfactory results. Our work has been directed almost entirely to the study of septic gunshot wounds, and we have isolated from these a large number of strains of bacteria, some of which we can identify while others are unknown to us. If one takes an ordinary sloped agar tube or, better, serum-agar and inoculates it with pus taken direct from a wound without any preliminary heating or other preparation either of the medium or pus, it is easy in 24 to 48 hours to grow isolated surface colonies of such bacteria as B. welchii or "malignant œdema," and then by subculture to isolate these strains pure. This isolation is easy, but at the same time it must be admitted that it is not so simple as is the case with most anaerobic organisms. It is not uncommon to find a contamination of a strain persisting through several subcultures from absolutely distinct colonies, and particularly is this the case with staphylococcus. Such cultures may, of course, be readily purified by heat, but we have avoided this method as far as possible owing to the impossibility of gauging at present the effect of heat upon the anaerobe. We have had little difficulty from contaminations with streptococci or colon bacilli; indeed, the conditions of the culture appear to reduce seriously the power of these bacteria to grow. We have been often struck by the inability of so-called facultative anaerobes to develop in our apparatus.

Having thus isolated a strain in pure culture it is very easy to study its behaviour upon the ordinary laboratory media, slope agar, agar stabs, broth, serum, gelatine, milk, and so on. Further, the action of the bacteria upon the various fermentable sugars or upon dye-stuffs may be determined and so valuable information obtained which may bear upon a more satisfactory classification of such strains.

It is well known that many anaerobes are affected in their morphology and biological characters—for instance, in the production of toxin—by the presence of sugar in the medium, and it is one of the advantages of the present method that dextrose is quite unnecessary for the furtherance of growth. We have thus been able to study these bacteria in a more stable condition than is usual.

Advantages of the method.—1. The method is clean. 2. It is rapid, the whole process being complete in about a quarter of an hour. 3. It is available immediately without any preliminary preparation or reagent other than hydrogen. 4. It is suitable for use with any laboratory medium without preliminary preparation of the medium. 5. It will grow the strictest anaerobes with great rapidity upon the surface of a solid medium. For instance, colonies of B. tetani in subculture upon serum-agar are visible in 24 hours.

We desire to express our thanks to Professor Bulloch for his kindly interest and advice on many points, and to Captain W. E. Bullock, R.A.M.C., for assistance and advice in the details of the method.

GUNSHOT WOUNDS OF THE SPINE; THEIR SURGICAL ASPECT.[1]

BY DONALD ARMOUR, M.B.TOR., F.R.C.S.ENG.,

HONORARY LIEUTENANT-COLONEL, R.A.M.C.; SURGEON-IN-CHIEF, THE QUEEN'S CANADIAN MILITARY HOSPITAL; SURGEON TO THE KING GEORGE HOSPITAL, TO THE NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, ETC.

THOUGH injury to the spinal cord is not a necessary consequence of gunshot wounds of the spine, it is obvious that the chief interest of such wounds lies in the commonly associated injury to the spinal cord and nerve roots. From a clinical point of view, therefore, cases of gunshot wound of the spine may be divided into two main classes:—(1) Those in which the functions of the spinal cord are not interfered with; and (2) those in which there is more or less interference with the functions of the spinal cord, with or without obvious injury to the vertebral column. In the second group the damage to the spinal cord is usually immediate—i.e., occurs at the time of receipt of the primary wound. But it is of the very greatest importance to remember that in cases where the spinal cord has escaped immediate damage, later or remote effects involving this structure may follow on the injury to the vertebral column. These later effects are produced by inflammatory products giving rise to thickening of the meninges; adhesions between the dura and bony wall, the dura, pia-arachnoid, and cord, with subsequent pressure due to the formation of a simple serous cyst of the meninges; by narrowing of the spinal canal through excess or misplaced callus; by blood clot, intra- or extra-dural; or as the result of continued suppuration.

If the injury to the cord be immediate it may be caused by:—1. The missile itself passing through the spinal canal, in which case the cord is wholly or partially divided. 2. Fractured portions of bone driven in against the cord, causing compression, contusion, laceration, or complete division. This would appear to be the most frequent cause of the cord injury. 3. Concussion. Under this head are included those cases in which, though neither of the preceding causes is operative, yet as a result of the vertebral column being struck certain structural changes are set up in the cord which are due to the jarring or commotion effects of the blow. Spiller has described this condition as "traumatic myelitis." The cord may show no external signs of injury either to inspection or palpation. Lieutenant-Colonel Gordon Holmes has recently described in his Goulstonian lectures the microscopical appearances found in such cases. He points out that the special character of these lesions is their diffuse and irregular distribution and their tendency to diminish gradually from the point of maximal disturbance. He concludes: "Whatever may be the exact mechanism of spinal concussion it must be admitted that a sudden

violent impact on the vertebral column can produce diffuse, irregular, and severe structural changes within the spinal cord. The factors which determine the severity of these lesions must be the momentum of the projectile, the part and surface area of the vertebra which it strikes, and the region of the spine which is wounded."

Now, is it possible to recognise clinically these three different results of gunshot wounds of the spine? For were it so, the question of operative interference would be made very simple, inasmuch as the first and third groups obviously would be excluded as beyond surgical relief. Naturally, we turn to X rays as likely to be the most helpful agent in determining the nature of the injury. But, unfortunately, it is in gunshot wounds of the spine that, in my experience, X rays are most unreliable. This is not to be construed in any way into a criticism of the skill of radiographers. It is simply a statement of the limitations of the X rays themselves.

In the first place they may not reveal any bony injury even when present. This is particularly true of the single flat plate. In all such cases it is necessary to have stereoscopic plates taken. I have had two or three such experiences. Again, the X ray plate never reveals the full extent of the bony injury within the spinal canal—i.e., where the damage to the cord is being produced. This is not to be wondered at when we consider how small a piece of bone may be the traumatic agent and how much it is overlain and overshadowed by the vertebra surrounding it. Therefore, in my opinion, the X ray plate should only be regarded as confirmatory evidence, or used to assist in the localisation of foreign bodies or for the purposes of bony localisation.

In considering operative intervention, the questions that will arise are in order of importance:—1. Will any benefit to the patient result from the operation? 2. Will his life be endangered by the operation? 3. Will he be made worse by the operation?

The condition should certainly not be made worse by the operation, provided it is undertaken by a competent surgeon accustomed to operate frequently upon the spinal cord. Unless the operator has had considerable experience in spinal surgery, it is very easy to overlook the site and cause of the compression. In these cases there are two levels to be considered, the neurological and the bony. The level of the lesion as indicated by the clinical symptoms usually does not correspond with the level of maximal damage. This is explained by the secondary changes which take place above and below the site of the injury in the cord. It is essential, in order that an operation should be perfectly successful, that all pressure on the cord from whatever cause be removed. Hence the necessity for a wide exploration both vertically and laterally. It is not only not necessary, but it is bad surgery to waste time in searching for a missile which has ceased to do damage and has passage beyond the immediate area of operation. Yet one sees too frequently a sort of surgical hypnosis produced by an X ray plate which shows a bullet or piece of shell still in the human body, though perfectly innocuous at the time. This hypnotic state is apparently only recovered from when the operator is able to produce to the admiring onlookers the piece of lead, while his own satisfaction reminds one of a certain nursery rhyme connected with one Jack Horner. The operation is ended quite oblivious of the fact that the pressure on the cord has in no way been relieved by this "plumbic" manœuvre.

In septic cases care should be taken not to open the dura if still intact. If already opened care should be taken not to break down any adhesions of a protective nature lest a septic meningitis be set up. Drainage along the usual surgical lines must be employed in septic cases. In those cases free from sepsis the dura should be opened for inspection of the cord.

The patient's life will not be endangered by the operation if a proper estimate has been made of his general condition beforehand. The chief and most frequent contra-indication is a general septic condition arising from the state of the kidneys and bladder, with persistent high temperature and perhaps rigors and a weak and irregular pulse. There is an added danger where the intercostals are paralysed, but with a skilled anæsthetist this may be obviated.

Will any benefit result from the operation? Let us consider what the operation may be expected to do. Briefly, it will relieve pressure, or, at any rate, remove any doubt as to whether continued pressure exists. If the spinal cord be not totally destroyed continued pressure may succeed in completing its destruction. Therefore operation is indicated: (1) To relieve pressure from depressed or displaced fragments of bone; (2) to relieve pressure from blood-clot or from extensive hæmorrhage, either extra- or intra-dural; (3) to relieve pressure and prevent further destruction from œdema by enlarging the constricted bony canal; (4) to remove the future danger of pressure from exudate and inflammatory thickening.

No operation will restore a cord in which complete transverse section has taken place. Nor will an operation benefit cases of concussion. Therefore we are brought back to the question upon the answer to which hangs the whole subject of operation: Are there any symptoms by which we can in a reasonable time determine beyond a doubt that we are dealing with a case either of complete transverse section or of pure concussion? In short, is there any symptom-complex which establishes beyond a doubt that the injury to the cord is irremediable? If there is not, then should not such a conclusion urge us to give our patient the benefit of an operation which experience shows neither materially endangers his life nor adds to his discomfort, but actually lessens his pain? It will at least allow us to determine the exact nature and extent of the lesion and to place the cord under the most favourable conditions for recovery of function, if recovery be possible. I have said a reasonable time. It is unfair to the patient and unfair to surgery to wait on and on till hope gives place to despair and then to call in a surgeon as a last resource to perform the impossible.

Harley-street, W.

LITERARY INTELLIGENCE.—The *American Journal of Gastroenterology* has combined with the *Proctologist* and hereafter will be published as the *Proctologist and Gastroenterologist*, from St. Louis. Dr. Rollin H. Barnes, St. Louis, will be managing editor and publisher.

THE FINSBURY DISPENSARY.—Owing to the war the customary biennial festival of this institution has been abandoned, and the Lord Mayor of London, as vice-president, makes an earnest appeal for funds to carry on the work. Contributions may be sent to him at the Mansion House, or to the secretary, Finsbury Dispensary, Brewer-street, Goswell-road, E.C.

ANÆSTHESIA FOR ENUCLEATION OF TONSILS.

BY J. BLOMFIELD, M.D. CAMB.,
SENIOR ANÆSTHETIST, ST. GEORGE'S HOSPITAL, ETC.

IT might well be imagined that there is nothing worth saying that has not already been said upon the question of anæsthetics for operations upon the tonsils. The operation now in vogue, however, for their complete removal makes a call upon the anæsthetist very different in degree from that hitherto demanded by the less radical procedure. Nor does it appear from recent correspondence in the *British Medical Journal* that this difference is on all hands fully recognised. Before the enucleation operation was introduced, an anæsthetic for the ordinary operation of tonsillectomy was a short and not formidable undertaking and one that was widely in the hands of the comparatively inexperienced. The present position is very different, and all anæsthetists will, I think, agree that to manage the anæsthetic with perfect success during the enucleation of both tonsils by dissection, with or without the use of guillotine or snare in addition, makes a tax upon experience and skill scarcely rivalled by any other operation of the same comparatively short duration. The reason for this is chiefly that most operators find their work hampered when freeing the tonsil if there is any contraction at all of the faucial muscles. To achieve this means procuring a degree of narcosis which might well be considered excessive in any other relation; it is actually a degree which places the child at the very limit of safety if, as is generally the case, chloroform is employed. There is a wide difference between the narcosis during which a tonsil can be rapidly cut across, as in the old days, without any reflex movement being evoked, and that which must be maintained whilst the organ is dragged or manipulated or dissected out of its very bed. It is true that some operators do not mind, or even prefer, an anæsthesia which permits the child to cough if blood remains on the back of the pharynx, an anæsthesia in which there is contraction of fauces to some extent during the manipulations which effect the dislocation of the tonsil from its bed. These surgeons, however, are in my experience in the minority, and most prefer that deep narcosis in which the fauces are absolutely slack in spite of severe pushing or dragging. It is this form of anæsthesia, therefore, that the anæsthetist is commonly expected to procure.

There are, of course, several means by which this can be done, all of them providing a perfectly satisfactory condition so far as the operator is concerned. They are not, however, all equally safe, nor do they all provide a sufficient anæsthesia for the same length of time. For example, in the days of the partial removal of tonsils by rapid operation "gas and oxygen" was often an admirable anæsthetic in adults. In suitable subjects it can be employed to-day for the complete removal, but only if this is to be effected without any dissection. Even if the dragging forward of the tonsil is necessary to ensure its complete encirclement by the guillotine or snare, then "gas and oxygen" rarely provides for a comfortable operation if both tonsils have to be removed. The case of ethyl chloride is similar, although it must be said for this anæsthetic that it is of the utmost service in children. Thus, in out-patient practice at St. George's Hospital we have for years employed it in young children who have both adenoids and tonsils removed, and we find it sufficient for complete removal when this is done by the guillotine, even when a small amount of dissection is required too. Naturally much depends on the expertness of the operator; and, moreover, there is not time with ethyl chloride for that attention to bleeding and thorough inspection of the areas operated upon which many operators prefer. That complete enucleation of both tonsils with the guillotine can be performed under these conditions, however, I have seen demonstrated in scores of cases where Mr. H. Barwell has shown the glands with their capsules after removal, and has allowed students to palpate the smooth evacuated beds of the glands in the fauces. It is not the ideal arrangement to handicap the operator in the least degree by the shortness of the anæsthesia, or to let the child cry or vomit or realise its surroundings before it is back in bed. Consequently ethyl chloride in these cases should, I think, only be regarded as a best possible under the circumstances of out-patient operation, and seldom as the anæsthetic of choice for in-patients or in private practice.

We come, then, to the question of a deep degree of narcosis obtained by the use of ether or of chloroform, or of both. From the point of view of bleeding and of mucous secretion, ether from any closed apparatus should, I think, be avoided in these cases. It used to be a favourite plan to induce anæsthesia by "gas and ether," keeping up the ether for five minutes or so till the patient was well charged with the drug, and then to give chloroform on an open mask for a minute or two, allowing the congestion previously induced to pass away. No doubt a quite sufficient narcosis is obtained in this way, and can be maintained efficiently by continuing chloroform through the tube of a Junker's inhaler whilst the operation is in progress. Yet I believe the condition is never so satisfactory as that obtained if the anæsthesia is induced without any, or only an extremely short, employment of closed apparatus.

Generally speaking, the best method, both for children and adults, consists, I believe, in giving a preliminary dose of atropine, gradually inducing a very deep degree of narcosis by a mixture of chloroform and ether, supplemented in some cases by a few minutes of open ether, and in some adults by a very few minutes of ether from a Clover's inhaler. There should be no congestion whatever by the time the operation begins, and the atropine prevents any undue mucous secretion. The anæsthesia thus obtained generally suffices for the entire operation. When it does not, chloroform is used from a Junker's inhaler or the open mask is reapplied. The same extreme degree of narcosis necessary during dissection need not be kept up whilst the bleeding is being stopped, in the case of operators who prefer to see deliberately to the stopping of all hæmorrhage after each tonsil is removed. The fear of a varying depth of narcosis is, I believe, largely a fetish. So long as there is no return to consciousness it is far better that the absolute absence of reflexes kept up during removal of the tonsil should lapse, whilst the hæmorrhage is receiving attention, to a condition in which the coughing reflex and the faucial reflex are present. To allow this is, moreover, to minimise the possibility of secondary or recurrent hæmorrhage, which is a mischance not to be ignored, at any rate after enucleation in adults of fibrous and adherent tonsils.

The importance of the position of the patient during operation varies completely according to the way in which the bleeding is treated. If, as with some operators, there is constant sponging, the position of the head is a matter of indifference, for no blood is allowed to descend. If, on the other hand, there is no attempt to stop the bleeding or to interfere with it in any way until the operation is completed, then obviously steps must be taken to avoid the possibility of inhalation of blood during removal of the second tonsil. It is better to achieve this by the safety of the position adopted than to have to rely upon a light degree of narcosis permitting coughing—better, at any rate, from the surgeon's point of view. Position, in fact, must be settled entirely in accordance with the operator's convenience, the anæsthetist realising, however, that in some positions, unless there is constant sponging, he cannot with safety provide a deep narcosis. Sitting, or lying with the head on one side, or with the head straight, are equally satisfactory in the case of operators accustomed to the respective positions, but the anæsthetist has certainly to vary his practice to suit the circumstances and to keep a keen eye upon the exact extent of narcosis maintained.

Harley-street, W.

PAIN IN RENAL AND VESICAL LESIONS:

ITS CHARACTERISTICS, ITS ANOMALIES, AND ITS MISGUIDING MANIFESTATIONS, WITH 12 ILLUSTRATIVE CASES.

BY DAVID NEWMAN, M.D. GLASG.,
CONSULTING SURGEON, GLASGOW ROYAL INFIRMARY.

(*Concluded from p. 729.*)

(*j*) IN *malignant tumours* of the kidney hæmaturia is the most prominent symptom, and is present frequently for a long period before pain is complained of. Hæmaturia is the symptom which most frequently induces the surgeon to make an examination of the loin, but, for the reason that it is unassociated with pain, it is often allowed to go on without a sufficient regard to consequences. The belief that malignant disease is necessarily associated with pain has, unfortunately, got a firm hold of the professional mind as well as that of the public. The absence of pain is therefore regarded as a good omen; but the absence of pain, from a diagnostic point of view, is a great misfortune. The most easily appreciated danger-signal is wanting. In the early stage pain is often absent, and sometimes especially in sarcomata, the whole course of the disease is practically painless. Suspicion is not aroused, and rapid progress takes place before the nature of the malady is even suspected.

CASE 9. *Unilateral painless renal hæmaturia during nine months, continuous at first, afterwards intermittent; blood from left ureter only, no shadow; round-celled sarcoma of left kidney; nephrectomy.*—The interest of this case is the entire absence of pain and the absence of swelling in either renal region. The diagnosis was made by a cystoscopic examination only. Nine months prior to examination the patient had a moderate symptomless hæmaturia, and he was able to resume work in a month or so. In four weeks thereafter he had a second hæmaturia when the bleeding became intermittent, being sometimes absent for a day at a time. Blood clots were passed. Otherwise there were no symptoms. The kidneys could just be felt and pressure did not produce pain. No shadow. Urine normal unless during the attacks of hæmaturia; bladder normal, but blood was seen escaping from left ureter only; healthy urine from right kidney. On exploring the kidney the upper pole was found to be occupied by a spindle-celled sarcoma about the size of a duck's egg. The tumour was firmly adherent to the diaphragm, so that the removal of the kidney was difficult.

In malignant disease the pain, when present, is most severe in the situation of the affected kidney, but, specially in the later stages of the disease, it may extend to distant parts. In character it is dull and aching, but may be paroxysmally increased, though not by movements of the body as in renal calculus. The suffering of the patient is generally more severe in scirrhous cancer than in acute carcinoma or sarcoma. It is frequently the cause of difficulty in micturating, even although the bladder is free from the disease. The pain presents great differences in its character; it may be at first slight, vague, and not constantly present, at other times it is entirely absent, or it may be severe and prolonged. In not a few instances the sense of discomfort in the lumbar region is the first indication of disease. Gradually, as the tumour increases in bulk, the suffering of the patient becomes more intense and more constantly present. At first dull in character, later it becomes lancinating, and may either arise spontaneously or be provoked by pressure, but it is seldom aggravated by movements of the body. When the tumour has attained considerable dimensions, or has invaded the tissues around so as to involve or compress the nerve trunks, the pain, instead of being limited to the lumbar region or hypogastrium of the affected side, may extend to the chest, across the middle line, or to the hip and lower extremities, which may lead to the disease being mistaken during this stage for sciatica or rheumatism.

The points to attend to in diagnosis are: 1. A swelling bulging forwards posterior to and covered anteriorly by the colon, resonant in front, dull behind, which retains a renal form and extends under the ribs. 2. Hæmaturia from one ureter, at first slight and at moderately long intervals, afterwards more frequent and severe, ultimately continuous and alarming. 3. Pain sometimes absent, and when present is constant and is principally due to pressure on nerves; the lumbar plexus causing pain like sciatica or intercostal pain like pleurisy. 4. Pulse and temperature normal. 5. No shadow, and no tubercle bacilli present.

(*k*) *Infarction* of the kidneys may be simple when a non-infected embolus is carried to the kidney and causes a thrombosis. Then pain may be induced by a secondary hyperæmia, but it is seldom severe or lasting. But if the embolus is infected a circumscribed suppurative nephritis is established, when the pain is sudden in its onset and stabbing in character and limited to the umbilical area in the early stage, but soon extends to the whole lumbar region. The abdominal walls become rigid and tender, and the kidney is difficult to palpate until pus forms, when a fluctuant swelling can be discovered. The case then presents the characteristics of a perinephric abscess already described.

(*l*) *Nephralgia* is probably a misleading term, and is as unsuitable as "essential neuralgia" as applied to the kidney. These sudden attacks of severe pain in the kidney are due either to an abrupt obstruction to the escape of urine from the ureter or to a temporary passive hyperæmia from torsion of the renal veins as already described under movable kidney or backward blood pressure in cardiac disease.

(*m*) *Aneurysm of the renal artery* seldom causes much pain, and when confined to the renal pelvis the only symptom may be hæmaturia. The pain

when present may be accompanied with pulsation and the condition is liable to be mistaken for rupture of the kidney with hæmaturia. Aneurysm of the renal artery not of traumatic origin is very rare.

(*n*) *Rupture of the kidney* is a common accident, and the symptoms depend upon the extent of the injury. When the spine is acutely bent upon itself, the kidneys, being firmly bound to the column, are made to describe a contortion similar to that of the spine, as a consequence of which not only may the convex aspect of the organ be lacerated and torn transversely, but the sudden jerk may force the kidney away from the middle line and tear the pelvis or the ureter. The blood may therefore escape in two ways—into the tissues surrounding the kidney, where, if the patient survives, it may give rise to perinephric inflammation and abscess, or by passing down the ureter it may give evidence of the injury the kidneys have sustained. But while laceration of the kidney may occur without a bruise in the loin, in the majority of instances a blow upon the lumbar region is the direct cause.

There is not much difficulty in diagnosing this form of hæmaturia. The history of a lumbar sprain or of a blow or crush on the loin, indicated perhaps by ecchymosis, leads one to suspect rupture or contusion of the kidney. Severe damage to the kidney may, however, exist independently of any injury to the other abdominal organs, and may of itself prove rapidly fatal; but in the majority of cases there is evidence of violence elsewhere, and there are symptoms of rupture of other internal organs, especially of the spleen and liver. Generally there will be marked and rapid collapse, pain in the course of the ureters as well as in the lumbar region, retraction of the testicle, difficulty in micturition, or even anuria.

When the rupture is on the surface of the kidney only the pain may be sharp and severe, but on account of injury to other parts it is difficult to estimate how far the renal lesion is to blame for the suffering. Renal colic may be induced by clots forming in the pelvis or ureter.

Frequently the production of pain is by no means easily explained, and may be due to reflex influences producing disorders in other organs. A good example of this is the pain observed in cases of movable kidney. On one occasion the pain may be of strictly renal origin and due to a transitory hydronephrosis; at another time there may be no dilatation of the pelvis of the kidney, but the patient may suffer from intestinal colic and great flatulent distension. The acute pain which is so commonly met with in diseases of the kidney so closely resembles the paroxysmal pain produced by spasmodic contraction of the intestine that the term colic has been applied to it, although quite unconnected with any disease of the alimentary tract. Frequently cases are encountered in which the kidney is the seat of stone, but the pain is not referred to the renal region, and being accompanied by nausea, loss of appetite, and vomiting, is very liable to be mistaken for intestinal or other forms of colic.

It would be well now to consider the points of distinction between paroxysmal pain in the abdomen due to conditions most likely to give rise to suffering simulating renal pain: (*a*) Spasm of the bladder; (*b*) uterine colic; (*c*) abdominal tumours; (*d*) in gall-stone; (*e*) in appendicitis; (*f*) intestinal derangement; and (*g*) in lesion of the lumbar and dorsal nerves.

(*a*) In *spasm of the bladder* it must be remembered that pain may be experienced in the urinary tract over an area distant from the actual site of the disease. We find that occasionally in impacted calculus of the kidney the pain is referred to the bladder; conversely, in diseases of the bladder the suffering may be most intense in the lumbar region. Spasm of the bladder is generally caused by the presence of some irritant, either in the viscus itself or in some other part of the urinary tract. Ulceration or inflammation of the kidney may produce such an intense spasm in the bladder that it leads the patient to concentrate his attention on the latter organ. Generally, however, spasm of the bladder is the result of the presence of a stone blocking the exit and preventing the escape of urine from the viscus; to ulceration, especially of a tuberculous nature; or it may be induced by morbid lesions in adjacent organs, such as the uterus or rectum. The pain is interrupted, there is a marked sense of constriction in the lower part of the pelvis, and the irritation may extend to the thighs, to the spine, or upwards towards the kidneys. The bladder may become considerably distended, and as it fills the agony increases, the patient becomes pale, the skin cold and clammy and covered by perspiration; and to distinguish it from the pain produced by renal disease the patient experiences much difficulty in passing urine.

(*b*) *Uterine colic* is mostly complained of at the menstrual period, but is not necessarily limited to it. Associated with sickness, nausea, and vomiting, it is very liable to be mistaken for renal colic; and if, in addition to these symptoms, there is numbness in the lower extremities, at the flexion of the thighs, and retention of urine, the diagnosis is difficult. In the great majority of cases, however, the pain of uterine colic is more severe in the pelvis, it is generally associated with tenderness over one or both ovaries, and there are evidences of deranged menstruation.

(*c*) *Aneurysm of the abdominal aorta and abdominal tumours* may or may not be accompanied by pain, but when they give rise to much suffering, especially if it is paroxysmal, the condition is liable to be mistaken for renal colic. On the other hand, renal pain may simulate aneurysm. In a large proportion of cases of movable kidney, and of renal calculus in emaciated persons, the aortic impulses are exaggerated, and at once attract attention; and, as the pain and pulsation are often associated together in the mind of the patient, the pain is referred to the area of pulsation, and so an incorrect description is given to the surgeon.

In movable kidney and in fixed displacement of the kidney the organ may lie in front of the aorta and be carried forward by each impulse. In aneurysm the pain is most severe in the back, but may extend down the sciatic nerve to the legs. As a rule it is constantly present and dull, with intermittent paroxysmal attacks of severe pain, which generally come on during the night or in the early morning. Beyond these characteristics there is nothing in the nature of the pain to distinguish it from renal colic; the condition must be recognised by the physical signs.

In *tumours of the abdomen* the character of the pain and its duration depend upon the situation and the nature of the neoplasm and the organ primarily involved. The attending symptoms vary greatly, but these and the physical signs are generally sufficient to guide the surgeon. The subject is, however, too large to discuss now.

(*d*) The pain of *gall-stones*, when impacted, very closely resembles that observed in renal calculus. It is, however, more marked in the epigastric region, is associated with jaundice, the voiding of gall-stones, and evidence of a deficiency of bile in the stools.

(*c*) In *appendicitis* the pain at the onset is not very severe, is accompanied by symptoms of acute disorder of the digestive organs, and is associated with swelling in the right iliac fossa, to which area the pain is at first limited; whereas in renal colic the pain is most severe in the lumbar region and downwards to the middle of Poupart's ligament.

(*f*) In the severe pain and colic of *perforation of the bowel*, of *hernia*, or of *intussusception*, the extreme and sudden prostration, the disposition of the patient to remain resting in a flaccid position with the knees flexed, the history of obstinate constipation, retraction of the abdominal walls at the onset, followed by steadily increasing abdominal distension, make the diagnosis easy. The physical signs and the nature of the pulse are generally characteristic.

(*g*) *Neuralgia of the dorsal and lumbar nerves* gives rise to pain in many respects resembling renal colic, and, indeed, a renal affection may be the immediate cause of the nerve irritation. When due to a perineuritis, spots painful to the touch may be found along the course of the nerves or their branches. These are generally a little to one side of the first or second lumbar vertebræ or about the middle of the crest of the ilium. The attacks of neuralgia are of frequent occurrence, and are unassociated with renal disturbance.

Differential Diagnosis of Affections of the Bladder Causing Pain.

(*a*) Cystitis; (*b*) tuberculosis; (*c*) tumours; (*d*) calculus; (*e*) distension—(1) enlarged prostate, (2) stricture, (3) tumour, and (4) calculus; (*f*) rupture; (*g*) pericystitis; and (*h*) cystalgia (coli bacillus lesion in women).

(*a*) *Cystitis* is generally associated with pain and frequency of micturition, but the amount of suffering depends upon whether the inflammation is mild, severe, or chronic, as well as the particular area of the bladder attacked.

In mild cases pain is not a marked symptom except during and immediately after micturition, when the pain is burning in character. In acute cases the onset is sudden, often with a rigor, the temperature is raised and may be distinctly febrile; the pulse is rapid, and the tongue is coated, the digestion disturbed, the stomach and intestine distended with gas, and the bowels constipated.

The patient is unable to sleep because of the pain and frequent call to micturate. As soon as the desire comes it must be gratified—the urgency is sudden and imperative. During the act the discomfort is great, but it is at its termination and for a variable time thereafter that the burning pain is most severe. The patient not only strains to get rid of the last drops of urine, but there is tenesmus.

This is the most important symptom. The bladder contracts powerfully, but the sphincter contracts as well, so that for a time nothing happens; the viscus cannot be emptied. Then the spasm at the neck of the bladder yields for a moment or two, and a few drops of urine are permitted to escape. Repeated evacuations of this kind occur and are associated with severe pain in the rectum, the perineum, and the point of the penis. After the viscus has emptied itself its muscular wall continues to contract and squeezes from its congested mucous membrane a few drops of pure blood.

Between the acts of micturition the patient suffers from a dull aching pain over the pubes, which is increased on pressure and by the gradual filling of the bladder, and as the organ becomes distended a sense of weight and tenderness develops in the perineal region.

Local pain shows itself in three situations: in the urethra, over the front of the bladder, and in the rectum and perineum. Pain in the suprapubic region is usually constant, dull, and aching, while in the urethra it is associated with micturition only—before and during the act, when the bladder is uniformly involved, and principally after the act, when the lesion is limited to the neck and the trigone. When the base of the bladder is seriously implicated, or if the inflammation is very acute, the pain may extend to the rectum and perineum.

Reflex pain may be referred to the kidneys, the umbilicus, the penis, the scrotum, and in rarer cases to the leg and foot. These reflexes have been already described. The symptoms associated with cystitis are: 1. The presence of pus in the urine with infective organisms; in acid urine, bacillus coli, tubercle bacillus, streptococcus pyogenes, and pneumococcus; in alkaline urine, staphylococcus pyogenes aureus and albus and mixed infections. 2. Hæmaturia, the blood corpuscles and colouring matter being well suspended in the urine and not readily forming a deposit. 3. Abundant mucous deposit. 4. Frequent micturition.

CASE 10. *Very painful and frequent micturition from staphylococcus infection of bladder; pyuria and hæmaturia; only 2 oz. of urine retained; acute catarrh of base; instillation of silver nitrate; suprapubic drain; lactic bacillus cultures and irrigation; cure in six weeks.*—The patient, aged 40 years, married, was admitted to the Glasgow Royal Infirmary on August 21st, 1912, complaining of very severe pain during and after the act of micturition, so severe as to bring on sickness and severe headache. She had an inclination to pass urine every half hour, but very little came away at each time, not more than 2 oz. The urine was muddy and bad-smelling, and was always tinged with blood. The urine when passed was alkaline, and contained pus in abundance and "strings" of blood. The only organism found was staphylococcus pyogenes albus.

August 27th, 1912: When under an anæsthetic the bladder was able to retain 4 oz. only, but after treatment to Sept. 6th 7 oz. were retained. An instillation of silver nitrate was used.

Oct. 19th: Cystoscopic examination. The floor of the bladder is inflamed, and there are a number of small prominences on the surface of the mucous membrane in the trigone. These are coated with phosphates, which are irregularly distributed, forming patches and edges. The pure white phosphatic deposit stands out in marked contrast to the deeply injected mucous membrane.

Oct. 29th: Suprapubic cystotomy was performed, and a mass of pulpy granulation tissue was removed from the neck of the bladder. Dec. 6th: Bladder washed out with boric acid solution and filtrate of saurine (lactic acid cultures) for five weeks, without much improvement in the local pain, but with great improvement in the condition of the urine. Yesterday patient had no pain and passed urine naturally. Frequency has greatly diminished. Dec. 10th: The wound is now closed. Symptoms have undergone sudden improvement. Frequency has been reduced to four or five times a day. Dec. 17th: Pain absent for a week. Dismissed. March 20th, 1914: Reported well.

(*b*) *Tuberculosis of the bladder* in the early stage is associated with frequent micturition, but seldom with severe pain. As cystic tuberculosis is almost always secondary to a renal lesion the early symptoms referred to the bladder are probably an example of reno-vesical reflex. It is when the base

of the bladder, especially the trigone and the neck, is attacked that pain becomes a pronounced symptom. When the infection becomes mixed, and the organisms cause decomposition of urea, the urine becomes alkaline; then the suffering of the patient is often excruciating during and immediately after micturition and is often accompanied by tenesmus. It is particularly severe at the end of the act and the area of greatest intensity is in the urethra and glans penis. As in other forms of cystitis the pain is referred to the renal region, over the sacrum, to the groin, and down the thighs.

The symptoms associated with tuberculosis of the bladder are: 1. Pyuria in acid urine with tubercle bacilli. 2. Evidence of tuberculosis in the kidney. 3. History of polyuria and small repeated hæmaturias. 4. Frequent micturition, at first without pain, afterwards with severe pain in the urethra and the point of the penis during and after micturition. 5. Remission of early symptoms for longer or shorter intervals. 6. Tuberculous lesion seen by cystoscope.

(*c*) *Tumours of the bladder* are not characterised by pain; in fact, the absence of pain is one reason why their presence is liable to be overlooked. The cardinal symptom is hæmaturia, often symptomless in the early stages. In hæmaturia the absence of pain is too likely to be looked upon as a good omen, but the absence of pain, from a diagnostic point of view, is a great misfortune. The most clamant feature of disease is wanting. The patient may be alarmed while the bleeding lasts, but when it stops and there is no pain he is willing to regard himself as cured by some drug he has taken; the bleeding recurs, and it is stopped by the same remedy, and again he is satisfied, whereas if pain had continued to be present, as in stone in the bladder, the patient would seek advice and procure relief from his suffering.

CASE 11.—*Hæmaturia during six months, at first small in amount, only occasional, and unaccompanied by other symptoms; later continuous, and accompanied by frequent micturition, finally by incontinence, and severe pain; malignant adenopapilloma occupying almost entire bladder, infiltrating deep structures and surrounding parts; suprapubic cystostomy for drainage; radical operation inadvisable.*—The patient, aged 52 years, was admitted to the Glasgow Royal Infirmary on Jan. 6th, 1913, complaining of hæmaturia of six months' duration. When it commenced it amounted to little more than a tinging of the urine with blood, and was only occasionally noticed. At first the bleeding was unaccompanied by pain, but gradually, as it increased, the patient experienced difficulty in micturition associated with a burning pain at the point of the penis. At first the pain and the bleeding were intermittent, but about a month prior to admission both became constant and increased in degree. Bright red blood clots were passed, and the pain was distinctly increased when the bladder was emptied. Together with these symptoms he had frequency in micturition, amounting to 12 or 14 demands in the 24 hours, and during the last month he lost control completely.

He never complained of pain in the back, but in the lumbar region, on the left side, there was considerably increased resistance, probably due to enlargement of the kidneys, and there was pain on deep pressure along the line of the left ureter.

Since ten days prior to admission the patient was confined to bed without any remission in the symptoms; indeed, with rest in bed the incontinence became worse. The bowels had been regular, but when they were moved considerable sharp pain had been experienced, and this for several days before he was admitted. Thoracic and abdominal organs were normal. The patient was very stout, the skin of a greyish colour and pale, but the mucous membranes and conjunctivæ were well coloured. Urine acid, specific gravity 1010, deeply blood-stained, contained much albumin and a deposit of red corpuscles, and a considerable amount of pus.

Jan. 7th: On account of bleeding I found considerable difficulty in getting a good view of the interior of the bladder, but after several washings a large tumour mass was seen nearly filling up the whole of the interior of the viscus. Jan. 9th: The patient suffered very severe pain and was losing a large quantity of blood, while the quantity of urine passed was very small. A suprapubic incision was made, and a large quantity of recent clot and old laminated thrombosis was removed. A fragment of the tumour was taken for microscopic examination. A drain was inserted and the bladder washed out. Jan. 20th: The bladder was carefully washed with boric acid solution three times daily. The bleeding was markedly reduced and the secretion of urine steadily increased, but the patient's general health was evidently failing rapidly. Under chloroform a careful and complete examination was made, when the tumour was found to be very large in size, almost filling the bladder, infiltrating the deep structures and surrounding parts. The kidneys were enlarged. Tumour an adenopapilloma. Feb. 3rd: Patient gradually lost strength and died this morning.

Pain may result from three causes—septic infection of the bladder, obstruction to the escape of urine, and infiltration of the bladder wall and the neighbouring structures by growth. The first mentioned is liable to occur after the use of instruments for the relief of retention, and when sepsis is established in such cases it is of an acute type and all the symptoms of severe cystitis are set up. The urethra may be blocked by blood clot or portions of the tumour, and pain may arise from over-distension, but the involvement of sensory nerve filaments in the new formation is the cause of greater suffering which is continuous and severe. It may be felt in the urethra, in the penis, over the bladder, in the groin, and down the leg. In the absence of cystitis, pain in the bladder, and radiating along the sciatic nerve and the anterior crural, not confined to the act of micturition, is a sign of malignant disease as distinguished from a benign tumour.

The symptoms associated with tumour of the bladder are: 1. Hæmaturia commencing gradually, a few drops at the end of micturition, without pain, afterwards with attacks of severe bleeding and passage of clots. 2. Frequent micturition without pyuria. 3. Portions of growth may be passed. 4. No crystalline deposit. 5. No X ray shadow. 6. Growth seen with cystoscope.

(*d*) *Calculus in the bladder* is indicated by pain, hæmaturia, and frequent micturition. The degree of suffering depends upon the nature and shape of the stone as well as the condition of the vesical mucous membrane. So long as the bladder is free from sepsis smooth uric acid calculi, even of large size, may occupy it for years without causing much inconvenience. But if infective organisms gain access, decomposition of urea leads to an alkaline reaction of the urine, phosphates are deposited on the surface of the stone, and in place of being smooth it becomes rough and irregular. This change in the character of the surface as well as the urinary sepsis contributes to the suffering of the patient. Therefore, if the stone is smooth and the mucous membrane normal, very little annoyance may be caused. This also happens when the calculus is fixed in a diverticulum if it is lodged behind an enlarged prostate.

Again, pain may be absent when along with a phosphatic stone there is bacillus coli infection of the bladder. The acid reaction of the urine causes the surface of the stone to be eaten into so that it presents a honeycombed appearance. This surface entangles the mucus which comes to envelop the calculus and so protects the mucous membrane

from irritation, while it also prevents the stone from being discovered by a sound. I published a case of this kind some years ago and said:—

CASE 12. On cystoscopic observation I found a white woolly mass occupying the floor of the bladder, the shape of a pigeon's egg, and about the same size. From its appearance and form one suspected the presence of a stone, but on passing a sound into the bladder no hard object could be found. Instructions were given to have the bladder washed out regularly twice a day for a week. At the end of that time another examination was made, and a clear phosphatic stone was found lying in the floor of the bladder covered with flaky mucus. In this case the stone had become completely enveloped in a mucous coating of considerable thickness, so that a sound could not possibly convey to the hand or to the ear the impressions we usually expect in a vesical calculus.

On the other hand, if the stone is composed of oxalate of lime, a rough, heavy, and jagged stone, severe and constant pain is experienced. The pain is increased by movement and relieved by rest, is aggravated during micturition, especially at the end of the act, when the mucous membrane is brought in firm contact with the stone, and may persist for some time thereafter.

The location of pain and the reflex pains are the same as in cystitis. The symptoms associated with calculus in the bladder are: 1. Hæmaturia at the end of micturition accompanied by pain. 2. Frequent and painful micturition. 3. Pyuria and crystalline deposit in urine. 4. X ray shows a shadow in the bladder area. 5. Stone seen with cystoscope.

(*e*) *Distension of the bladder.* When due to atony its wall is sclerosed and its muscular elements are degenerated, sensation is impaired, and little pain is complained of. Likewise, when the obstruction to the escape of urine is slowly developed, as in stricture or enlarged prostate, a dull aching pain in the region is all that the patient suffers. It is when the obstruction is sudden, as in impaction of a calculus or blocking with blood clot, that severe pain is experienced, and this increases in degree until relief is obtained. The most common causes are stricture, enlarged prostate, calculus, and tumours of the bladder.

(*f*) *Rupture of the bladder* causes severe pain in the lower part of the abdomen with a great desire to micturate, and may be the result of external violence, over-distension, or the misuse of instruments. Spasms of severe pain come on at intervals, the abdomen is rigid and tender on palpation, and when a catheter is passed only a little blood comes away. There is marked shock. The history of injury clears the diagnosis.

(*g*) *Pericystitis* may follow injuries to the bladder. When an abscess forms in the space of Retzius there may be intense pain and strangury and great suprapubic tenderness, high temperature, and rigors. Pain is not influenced by micturition, is increased by pressure in front, and the urine is clear unless the abscess ruptures into the bladder. The pain is distinctly local.

(*h*) *Cystalgia* I cannot recognise as a separate disease, although it has been frequently described as such. Cases are undoubtedly met with where women suffer severe burning pain extending sometimes to the perineum, increased when sitting, and travelling is rendered very difficult, causing agony. In these cases a lesion is always found with the cystoscope or the urethroscope.

In addition to the condition just described, a form of irritable bladder is common where the patient is distressed by frequent micturition during the day, and during the night there may be occasional incontinence. The only complaint may be pain and frequency, and although it may be most troublesome and inconvenient to the patient, from the nature of the illness she is liable to hide or minimise her suffering rather than seek medical advice.

The cystoscope shows in many cases congestion around the neck and some hyperæmia of the mucous membrane of the first portion of the urethra; the urine contains a large quantity of mucus and bacillus coli, but no pus. With suitable local treatment the symptoms disappear.

ON THE CONNEXION BETWEEN "SOLDIER'S HEART" AND HYPERTHYROIDISM.

BY FLORENCE A. STONEY, M.D., B.S. LOND.,
HEAD OF THE X RAY DEPARTMENT, FULHAM MILITARY HOSPITAL.

I WISH to point out the very close connexion there is between hyperactivity of the thyroid gland and the tachycardia and breathlessness seen in cases of "irritable heart" and "soldier's heart." This association is a most important one, since the thyroid gland is eminently amenable to treatment.

These cases of "irritable heart" conform to slight cases of Graves's disease. The pathological condition of the thyroid gland in Graves's disease shows the gland cells irregularly massed, no regular acini, but a mass of actively secreting cells, pointing to some bacterial or other stimulus. This degeneration may occur in a gland which is not enlarged.

There are probably several chemical substances secreted by the thyroid; these different substances may produce the different varieties of the disease, but they are all derived from the thyroid. This is proved by submitting such cases to X rays in order to atrophy the gland. The gland can be reduced to any required and regulated extent, with the result that as the gland grows smaller all abnormal symptoms disappear and the man is fully restored to health. Malignant cells which are actively growing are some of the most easily atrophied by X rays; glandular cells are also readily affected. The thyroid gland in exophthalmic goitre is much more easily affected by X rays than the thyroid of a quiescent bronchocele, which may be explained by the glandular cells in exophthalmic goitre being in a very active condition.

We know the thyroid is excited by mental stress and danger, fright being a not infrequent cause of the onset of Graves's disease. Such conditions are produced in a very severe degree by the war strain—by the responsibility, the danger, the noise, sudden explosions near by, with the accompanying horror and nervous shock, and the constant strain on the attention, added to severe physical strain. History tells us that for years after the Franco-German War the people who remained under the German heel in Alsace-Lorraine were to a marked extent subject to exophthalmic goitre. There are many cases of shell shock which show no signs of Graves's disease, and where one can only suppose the thyroid has not been adversely affected; but other cases show symptoms of hyperthyroidism definitely dated by the patient as commencing only after one such definite shock, or after burial by an explosion.

The tendency to thyroid degeneration is one which runs in families, hyper- and hypo-thyroidism appearing in different members of the family, or in

the same individual at different times; that is, the gland in some families shows marked inability to withstand adverse conditions—it is unstable, and if exciting causes such as overwork, overworry, or pyorrhœa occur, then it degenerates. There are other causes besides nerve strain which help to cause the actual degeneration of the gland. The fact that one cause is to be sought in toxins from the alimentary canal is proved by Sir Arbuthnot Lane, who cures these cases through stopping intestinal stasis by his operation of short circuiting. It is noteworthy that dental caries, tartar, and pyorrhœa alveolaris are, or have been, present very commonly in these cases, but not universally. The thyroid condition persists after all the teeth are extracted; but in X ray work I have found those patients who have had their mouths thoroughly cleansed respond very much more quickly to treatment than those in whom constant oral sepsis persists. I therefore think there is a large probability that pyorrhœa is a common source for the causal germs, though not the only one.

Early cases, such as we are seeing in the base hospitals as a result of the present war, are often unrecognised as to their true nature; above all, the connexion of the various groups of symptoms with changes in the thyroid gland and the importance of this connexion are unrecognised. The result is that these cases drift on for months and months. The patients are often looked upon as being the subjects of shell shock or as neurasthenics, or sometimes as cases of early phthisis, and are sent out much in the same condition as when they came in, to pass almost at once into some other hospital.

That X rays, when properly and vigorously applied, are a specific for exophthalmic goitre I am quite convinced. I have treated these cases with X rays during the last seven years, and the results are most cheering. I have taken over the leavings of both surgeons and physicians, and enabled patients to resume an ordinary healthy life. One thing which cannot be cured is the heart which has been overstrained and dilated for several years; it never becomes quite as sound as it was before, the heart muscle remaining weak, so that the organ is more easily overstrained again than a healthy heart. But I have known patients lying up for weeks in hospital and at home who did not improve, or very slightly, and who did get well with X rays even in the adverse conditions of long daily toil. Some of my old cases come back to me for a couple of X ray exposures when they feel run down and in need of a tonic. I have seen several cases labelled "debility" or "neurasthenia" that were really slight cases of hyperthyroidism which did not respond to ordinary medicinal treatment, but which got rapidly well when the thyroid gland was made a wee bit smaller.

Exophthalmos is often a late symptom in this disease of the thyroid gland, and goitre may never be present.

Many cases with simple enlargement of the thyroid (bronchocele) show no symptoms of hyperthyroidism for a long period, as there is no excess of thyroid secretion into the blood; but a time comes when some of them begin with tachycardia, tremors, &c., indicative of a further change in the gland, and the pathological finding in such cases is that besides the ordinary colloid and gland cells found in every bronchocele there are areas which show alteration of tissue exactly similar to that found in the gland in exophthalmic goitre, evincing that the symptoms of hypersecretion are not due to the bronchocele but to the secondary degeneration of the gland. Thus, one may speak of Graves's disease or hyperthyroidism which is either (*a*) primary or (*b*) grafted on to a pre-existent bronchocele. I have now treated over a hundred cases which include both these groups.[1] Most of the cases in the present war are primary, no goitre having been present apparently before enlistment. There are several groups into which these early cases of hyperthyroidism fall according to which symptoms are the more prominent.

Group 1.—Tachycardia. This is perhaps the most usual group met with. These patients come in for breathlessness or fainting, often quite definitely associated with the effects of some particular shell which has burst in their near neighbourhood or shortly after they were buried by some explosion, and they say quite definitely that they were all right until that sudden great strain. Some have been rendered unconscious by the shell; others have not had such a severe shock. Some have found the strain of training too great, and have been much exhausted by the long marches or other heavy physical work. They suffer from giddiness and weakness. The heart-beats are most characteristic: the frequency may be normal or only slightly quicker than normal when lying down, but on sitting or standing the rate goes up to 90-100 or over, only to quiet down again by several beats on resuming the recumbent posture. The heart is often dilated. A skiagram shows dilatation of the right auricle and rounding of the ventricles. The action is tumultuous. The first sound is short and wanting in tone; this is its main characteristic. The heart may be irregular in force and rhythm, showing poverty of cardiac action. Any murmurs present, though often attributed to valvular disease, are hæmic or come from incompetence due to over-distension and disappear when the heart becomes quiet, unless there has been previous endocarditis from some other cause, such as rheumatic fever. The pulse is markedly collapsed between the beats. There is no œdema of the legs till late in the disease when the heart is failing. Such heart failure, with œdema, is seen in civil practice where the heart muscle has been overstrained for years and is consequently degenerated, but is not seen in these slight early cases, the product of this present war. These patients feel very weak; they suffer from dyspnœa, præcordial pain, palpitation, giddiness, and fainting. Even after treatment, when the heart has resumed its normal beat, the skiagram shows a rounded condition of the whole organ.

Group 2.—Manifest marked perspiration, and tremor which becomes more marked on the least effort or excitement. The tremor is a fine movement of the hand or may be general, or it may show itself in larger jerky twitchings of the muscles.

Group 3.—This group exhibits mainly nerve symptoms. These patients tell you their nerves "have gone to bits," and they are put down as cases of shell shock; but besides the effect that shell shock seems to have on the higher cerebral centres, there is this definite action, which it may have, of upsetting the thyroid gland. These patients are "jumpy" and twitch, they have bad dreams, they sleep badly, the pulse becomes unduly rapid on the least excitement, they dread everything. The medical attendant says they are neurasthenics, but what is meant by this word, and what is the underlying physical condition? Does it not mean hyperthyroidism, whether due to loss of nervous control, nervous exhaustion, or from intestinal toxin, or other cause?

Group 4.—This group shows enlargement of the thyroid as the first sign. This is soft and bilateral in early cases, and may or may not have been noticed by the patient before admission. The swelling is only unilateral where there has been previous benign bronchocele. This enlargement may be so slight as only to be evident when the patient puts his head well back so as to stretch the sternomastoids, and then the fullness becomes evident.

Group 5.—Eye symptoms. Exophthalmos may be the first thing noticed. The absence of wrinkles on the forehead and v. Graefe's sign of jerking lids are more common.

As the cases progress more and more symptoms from the above groups gradually develop. By the time the patient reaches the base hospital two or more groups are usually present, and even then the

[1] See THE LANCET, August 10th, 1912, p. 370, 48 cases reported by me; also Brit. Med. Jour., August 31st, 1912.

true nature of his condition may not be recognised. Common combinations are: tremors, nerves shaky and skin moist; or breathlessness, tachycardia, weakness, and sweating; or nervous twitchings, no wrinkles in the forehead, with raised pulse-rate—in fact, the above five groups may be combined in any proportion. These cases also show some general conditions: they lose weight, feel "good for nothing," are despondent and irritable, and worried by small causes. Nearly all are constipated, though the bowels may be relieved daily, and most of their mouths exhibit various degrees of pyorrhœa and of dental caries.

Treatment.

Of methods of treatment there are three: rest and medicine; surgical treatment; and X ray treatment. If complete success is to be obtained, the general condition of the patient must be attended to, as well as the local affection.

X ray treatment.—This does not deal with the primary cause of the disease, but cures the patient. It is the way *par excellence* to lessen the thyroid gland to any desired extent. The points about this treatment are the following: 1. There is no shock or danger to life as in operation. 2. The reduction in the activity of the gland can be carried on to any desired extent, so as to bring the secretion back to the normal amount. Beyond this myxœdema would be caused, therefore one has to be careful not to go too far. X rays are much more accurate than operations on the neck, as the dose is adjusted exactly to fit each case. 3. There is no pain or unpleasantness. The patient merely lies on a couch and has the X rays applied to each side of the neck over the gland; he does not feel anything and sometimes goes to sleep during the treatment.

One disadvantage of X ray treatment is that it requires several sittings spread over a couple of months or more according to the severity of the case. The length of treatment depends on many conditions; the more X rays are pushed the quicker the patient gets well.

In hospital these soldiers are ideally placed to get well. They are away from their original source of worry and nervous shock, they are well fed and cared for, and they can take rest to allow the heart to recover tone; they are, moreover, away from home worries, and have no daily duties which must be done no matter at what cost to themselves.

Besides having the secretion of the thyroid diminished, these patients require their health to be built up in every way possible. One serious source of delay is that it takes on an average from six weeks to two months to get their mouths cleansed, which is a great, almost an essential, help to treatment. In many cases some pyorrhœa is left behind, which hinders the cure. Another point to be attended to is either thorough abdominal massage or daily aperients to overcome the universal intestinal stasis, of which the patient does not complain, but which is always present. Rest is useful to restore the weakened heart, but I do not keep my patients constantly in bed except where such weakness is very acute; many of them have had months of bed without result before coming to me and are thoroughly weary of it.

The treatment I pursue is to apply the X rays as vigorously as is compatible with safety to the skin. At first I did not filter and got much mild dermatitis, now I give much bigger doses filtered. One Sabouraud dose through one or two millimetres of aluminium as a filter to each side of the thyroid weekly requires about 20 minutes. The results are in some cases slow, in others astonishing. A languid, tired, irritable, jumpy patient gains week by week in mental quietude, gets better tempered, more placid, and feels better and stronger; sleep, digestion, and pulse all improve, and he gains weight. The heart is one of the earliest organs to respond; it first becomes regular, then slows down and resumes its normal size while regaining tone in the first sound. The throbbing in the carotids disappears and there is a strong, full, regular pulse, steady and quiet even in the upright position, though for some weeks longer any excitement or emotion raises the rate. After some time exophthalmos is no longer evident, rarely does it persist. The goitre first becomes softer and then diminishes in size till the neck becomes normal. Even patients who do not show much improvement while undergoing the rays show marked improvement a few months later. The only risk is of temporary pigmentation of the skin which may even go on to slight dermatitis, and later in a few cases to telangiectasis.

The treatment requires much patience and attention to detail on the part of both practitioner and patient, but the good results obtained are quite worth the time and trouble spent, and if more widely used would bring many back to health who now drag on an existence for many months in miserable weakness and ill-health. The difficulties are the time required, and that patients feel so much better that they are apt to be discharged before being fully cured.

The main facts I wish to lay stress on are the following. 1. Fine tremor in a young man is not normal; a healthy soldier returned from the front does not so tremble. 2. Excessive perspiration with tremor is not normal. 3. Great nervousness, dread, and jerky twitchings are not normal. 4. A pulse habitually over 90 is not normal. 5. The condition called "soldier's heart" and "irritable heart" must be caused by something. These are not psychical conditions, to be looked at and labelled, but beyond the reach of help. No; they are one and all suggestive of oversecretion of the thyroid gland, and when so caused can be cured by partial atrophy of the gland. If seen early they can quickly be cured; if left for months they take longer; but they can be cured as certainly as an abscess is cured by opening and draining it.

The following are notes of four cases at Fulham Military Hospital:—

CASE 1.—Private, aged 22. Perfectly well until he enlisted on June 6th, 1915. He felt greatly exhausted while training, finding the long marches especially trying. On July 23rd he was sent to Fulham Military Hospital suffering from "breathlessness and tachycardia." He was kept entirely in bed, but at the end of six weeks there was no improvement. He was intensely nervous, weak, and pale. A skiagram showed a rounded, tumultuous heart.

When I saw the patient I diagnosed hyperthyroidism of the nervous and cardiac types. On Sept. 4th I started X ray treatment to the thyroid. I did not keep him wholly in bed. He showed slight fullness of the neck, there was no pyorrhœa, he was very breathless, his pulse recumbent was 136, and he was so scared and nervous that I could hardly get him to lie quietly on the couch for the first treatment, though later he came willingly. During the next week he had his second treatment; he was still breathless; pulse 104 recumbent. On Oct. 18th, after seven treatments, he was sent on furlough for a month; therefore X rays were stopped. His neck was three-eighths of an inch smaller; there was no dyspnœa or tachycardia; he felt strong and was able to be up all day, and in manner was very much quieter. All this was accomplished in six weeks.

When seen one month later the patient was back at his depôt. He told me he was so well that he could not get his discharge from the army. He was slightly nervous in manner, the pulse standing was 72, all other symptoms were completely gone, his weight had gone up, and he felt strong

and well. He went out rather too soon, and runs some risk of relapse in consequence.

CASE 2.—Private, aged 25. In France from November, 1914, to April, 1915; through Ypres and Neuve Chapelle; sent home in April, 1915, for rheumatism, bronchitis, and frost-bite. On Sept. 2nd he entered Fulham Military Hospital, and was said to be neurasthenic. Weight 8 st. 10 lb. He perspired, had headache, the eyes were misty, but vision was normal; he was losing weight, but his collars had been tight of late.

An X ray examination showed the rib cartilages ossified, and the heart small, rounded, and tumultuous. On Oct. 18th the note of Dr. R. McNair Wilson was: "High blood-pressure, marked vaso-motor symptoms, no gross cardiac lesion, nervous, toxæmia." On Oct. 25th the patient's medical attendant, Dr. R. Dainty, and I agreed that the symptoms were really due to hyperthyroidism, so I started X ray treatment. The patient then had fine tremor, perspiration, pyorrhœa; the pulse was irregular in force and rhythm, 92 recumbent; there was slight goitre. Nov. 11th: Third treatment. Pulse regular, 76 recumbent, pyorrhœa still, goitre less, no tremor, no perspiration, felt better. On Dec. 16th the patient had had seven treatments, delayed by dermatitis. Jan. 8th, 1916: No further treatment. The dermatitis had disappeared. The patient had improved very markedly since the treatment began, and had recovered a healthy condition. He was no longer depressed and good for nothing, and was feeling strong —"better than before Neuve Chapelle." He weighed 9 st. 9 lb., and the pulse was regular, 80 standing. The headaches, tremor, and perspiration had all disappeared, and the patient was able to run without getting unduly out of breath; the goitre had disappeared, and the neck measured one inch less than when X rays were begun, two and a half months previously. The case had responded very well to treatment, and the patient has now returned to his regiment.

CASE 3.—Private, aged 31. In France from November, 1914, to May, 1915. He was buried by the explosion of a shell. Complained of sore feet and excessive perspiration in April, 1915. Admitted to Fulham Military Hospital in June, 1915. He was sent to me to be treated for very excessive perspiration, chiefly in hands and feet. Local treatment did not succeed, and I noticed that the pulse varied from 68 to 100, while he had distinct fine tremor, I therefore changed the treatment to giving X rays over the thyroid gland. After five treatments the tremor was gone and the perspiration had much diminished. The pulse was 80 standing. The patient was discharged, but he would have been better with a few more treatments.

CASE 4.—Private, aged 21. In France from October to December, 1914; sent home wounded. In France again from March to October, 1915. Admitted to Fulham Military Hospital on Oct. 9th, 1915, the case being diagnosed as "palpitation and disordered action of the heart." The patient had suffered from palpitation for four months, which had gradualiy been getting worse, from shortness of breath, and from dizziness and headache. Oct. 26th: Præcordial pain. The heart-beats were hurried, the pulse-rate was 96, and there was fullness of the neck suggesting enlargement of the thyroid. It was decided to adopt the X ray treatment. First treatment: Condition as above. No heart murmurs. Pulse 104, regular; goitre large, soft, and uniform; the neck measured 14 inches. Tremor and perspiration were present—palpitation frequent. Nov. 9th: Third treatment. The patient felt better and the heart was quieter; pulse 100. Dec. 16th: Eighth treatment. Only one attack of palpitation during the last week; goitre smaller, 13⅛ inches; tremor nil; pulse 88 standing. The patient's medical attendant considered him to be a great deal better. Dec. 29th: Tenth treatment. Occasional palpitation; perspiration and tremor gone; pulse 92 standing; goitre 13⅛ inches, almost disappeared; no dyspnœa, dizziness, or headache; occasional pain in the chest still. The patient was up and about all day. The septic teeth and digestive trouble had delayed this case. After a month in a convalescent home the patient has returned to his regiment and is reported to be quite well.

I am now treating with X rays over 20 cases of tachycardia or shell shock each week, and several patients have already been discharged back to their regiments.

I am indebted for the above cases to the kindness of the other medical officers of the Fulham Military Hospital who have allowed me to treat their patients, and especially am I grateful to our commanding officer, Major C. T. Parsons, R.A.M.C., for his constant help and interest in everything which concerns the department.

Nottingham-place, W.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION FOR THE STUDY OF DISEASE IN CHILDREN.

Exhibition of Cases, Tracings, and Specimens.

A MEETING of this section was held on March 24th, Dr. R. HUTCHISON, the President, being in the chair.

Dr. HUGH THURSFIELD showed a case of Rickets in a girl aged 2½ years, with old fractures of both clavicles, both femora, and both humeri, and recent fractures of right humerus and left fibula and tibia. She had marked rickety deformity of the thorax.

Dr. H. C. CAMERON showed a case of Osteogenesis Imperfecta in a girl aged 5 months. Three other children in the family. No history of fractures in any relatives. Born at full time. The baby was small, though not ill-nourished. On admission there was tetany of the hands, and the spasm could be made very marked by rendering the hand cyanosed by the pressure of an elastic band around the upper arm. In a few days this disappeared. Until admission the baby was breast-fed. The shape of the skull was typical. The bones of the skull generally were very thin, and in many places yielded on pressure. The ossification was most defective in the lateral parts of the skull, which were formed largely in membrane, forming persistent lateral fontanelles of considerable size. The skull presented a superficial resemblance to that of hydrocephalus of mild degree. The limbs were somewhat curved and a little short. A thickening due to callus could be felt in the shaft of the right femur. The sclerotics were somewhat blue.

Dr. J. L. BUNCH showed, amongst others, a case of Papulo-necrotic Tuberculide.

Dr. J. D. ROLLESTON showed a case of Transient Hemiplegia in Diphtheria and Diphtheritic Onychia. The patient, a boy aged 5 years, was admitted to hospital on Oct. 6th, 1915, with severe faucial diphtheria on the third day of disease. 20,000 units of antitoxin were given on admission, 16,000 on the 7th, and 12,000 on the 8th. The throat became clean on the 11th. An urticarial rash appeared at the injection site on the 12th, and persisted till the 15th. The same day the heart, hitherto normal, showed some slight left-sided dilatation and an occasional extrasystole, and the child vomited. On the 16th triple rhythm developed and the liver became enlarged. On Nov. 2nd the voice became nasal. On the morning of the 3rd, the thirty-first day of disease, a circinate rash appeared on the limbs. Temperature 97·8° F. During the day the patient complained of abdominal pain, and at 10 P.M. became very pale and almost pulseless. At 1.30 A.M. the face, eyes, and arms twitched, and between 4 A.M. and 6.40 A.M. he had general convulsions. At 11.20 A.M. he was found to have complete loss of power in the right upper and lower extremities. There was slight facial palsy. The right abdominal reflex was less marked than the left. Both plantar reflexes were flexor. There was no ankle clonus. The knee-jerks were absent. He seemed to understand what was said to him, but could not speak. The left index, middle, and ring fingers each showed a bulla on the terminal phalanx. At 7 P.M. he had recovered some power in the right upper limb, but the lower limb was still paralysed. The right plantar reflex was now extensor. He could now speak a few words. On the following morning he had quite recovered his speech and could move his right arm and leg freely. The right plantar reflex was still extensor, but became flexor the next day. The voice remained nasal until Nov. 29th, but no other nervous symptoms developed, and when he was allowed up on Dec. 3rd, the sixty-first day of disease, he could walk without support. In spite of a variety of local applications the lesions in the fingers showed no tendency to heal, but sloughing took place, especially in the middle finger. No membrane was seen at any time. There was no constitutional disturbance nor any rise of temperature. On Jan. 19th, 1916, a culture taken from the lesion on the middle finger showed numerous groups of diphtheria bacilli, and 8000 units of antitoxin were injected. Within a week the lesions, which had been in existence for two and a half months, had completely healed.

Dr. E. B. GUNSON showed a case of Gangrene of the Leg following Diphtheria. The patient, a boy aged 6 years, was admitted to hospital on Jan, 5th, 1915, with severe faucial diphtheria on the fourth day of the disease. He was given 20,000 units of antitoxin on admission, and again on the following day. On the seventeenth day the pulse became markedly irregular, the onset of arrhythmia being followed by marked increase in cardiac and liver dullness. On the eighteenth day there was a sudden onset of acute pain, referred to the right popliteal space. On the following day a ring of discolouration appeared below the knee and the leg became cold. Gangrene of the right small toe and outer aspect of the foot developed on the twenty-second day, and gradually involved the whole of the leg below the level of the knee-joint. Sloughing of the skin appeared at the line of demarcation on the forty-ninth day. Palatal, pharyngeal, and diaphragmatic palsies developed during the fifth and sixth weeks. Amputation of the right leg was performed by Mr. H. S. Clogg, the patient ultimately making a complete recovery.

Dr. C. O. HAWTHORNE showed tracings of a case of Rapid Respiratory Rhythm apart from other Evidence of Disease. The patient, a girl aged 8 years, was under observation in hospital for some six weeks, and no evidence of organic disease was discovered. The respiratory rate was constantly quickened (60 to 80 per minute), and occasionally exceeded the pulse-rate; when the child was asleep, however, it fell to 20 to 25. There were no other symptoms, and save for the rapid breathing the child seemed to be in a normal state of health. When she left the hospital the respiratory rate was about 40 per minute.

Dr. E. A. COCKAYNE showed a case of Paroxysmal Hæmoglobinuria. The patient, a boy, lived abroad until March, 1915, where he suffered slightly from malaria. There was a history of a miscarriage before he was born, and of a still-born premature child two years ago. The first attack of hæmoglobinuria occurred the day after landing in England. He was free in the summer, but in the autumn with the onset of cold weather attacks had occurred fairly often. Previous to the attack the ears and feet felt very cold, but there were no definite phenomena of Raynaud's disease. The child was thin and very anæmic. No definite stigmata of congenital syphilis. The urine during an attack was coffee-coloured and contained hæmoglobin and methæmoglobin, but no red corpuscles and no casts. The Wassermann reaction was strongly positive.

Pathological specimens were shown by Dr. ROLLESTON and Dr. H. C. CAMERON.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF MEDICINE.

The Soya Bean (Glycine Hispida) and its Uses in Physiology and Medicine.

A MEETING of this section was held on March 3rd, when Dr. W. G. SMITH read a paper on the Soya Bean (*Glycine Hispida*) and its Uses in Physiology and Medicine. Attention was drawn to its important dietetic and economic applications, which admit of considerable extensions if its cultivation be extended in our colonies, especially in South Africa. The seeds are free from starch and sugar and have been utilised in the treatment of diabetes. The chief topic of the paper referred to the striking discovery by Takeuchi, a Japanese *savant*, that the bean contains a specific ferment, urease, which rapidly converts urea into ammonium carbonate. The general principles of enzyme action were briefly mentioned, and the modes whereby they operate. The relations of ordinary urea to ammonium cyanate and of sulphur urea (thio-urea) were discussed, and the mutual reversibility of the process in each case was experimentally shown. The almost immediate influence of urease in converting urea into ammonium carbonate was demonstrated, and it was pointed out that urea had recently been discovered in a number of plants, up to as much as 3·5 per cent. in a fungus. A practical point in connexion with urease is its application to the quantitative estimation of urea. The most rapid methods of estimation for routine work are: (*a*) The hypobromite method. (*b*) Folin's process with $MgCl_2$ and HCl. (*c*) The most accurate method is by urease. The ammonia is absorbed by decinormal sulphuric acid.

Dr. T. P. C. KIRKPATRICK asked whether the estimation of urea could be carried out in clinical work, or must the urea be in a pure state.

Dr. A. R. PARSONS complimented Dr. Smith on the clearness with which he had dealt with a somewhat abstruse subject. He could confirm the almost invariable presence of starch in so-called "diabetic foods"—he had once found as much as 60 per cent.—and thought soya bean might prove very useful in this respect. He was very glad to hear of this method of estimating urea, as he had found the hypobromite method unreliable. He would like to know how urease was prepared commercially, and where it could be obtained.

Dr. J. CRAIG said that soya bean had been in use as a cattle food for some time. In some cases cattle had died in a rather mysterious way, and he would like to know whether urease could act on any other nitrogenous substance.

Professor A. E. METTAM asked whether the term "glycine" indicated any connexion with the substance glycin which combined in the kidneys with benzoic acid to form hippuric acid.

Sir J. W. MOORE recalled the fact that a proportion of carbohydrate in the diet was very desirable in diabetes.

Dr. SMITH, in reply, said that the estimation of urea by urease was quite applicable to clinical work, and was, in fact, a very simple and easy method. In the case of cattle urine an estimation was afforded of the allantoin nitrogen also. He considered the name "glycine" quite independent of any other similar term.

SECTION OF PATHOLOGY.

Exhibition of Cultures and Specimens.

A MEETING of this section was held on Feb. 18th, Dr. R. J. ROWLETTE being in the chair.

Dr. W. D. O'KELLY exhibited cultures which were prepared in connexion with the work he was carrying out under Professor E. J. McWeeney for the Medical Research Committee. They illustrated the culture points of differentiation between the bovine and human types of tubercle bacilli. He fortunately succeeded in making direct cultures on the egg medium, thus getting over the difficulty of isolating the organisms without animal inoculation. The only difficulty now was to secure the material uncontaminated; if this were obviated a high percentage of successful direct cultures should result.

Mr. R. M. BRONTË exhibited cultures of tubercle bacilli of human, bovine, and avian type.

Dr. W. BOXWELL showed organs removed from a female patient aged 28, on whom Mr. Henry Stokes had previously performed an operation for the cure of ectopia vesicæ. After removal of the uterus, the ureters had been successfully transplanted into the rectum, and for some time the patient had done very well. Subsequently, however, one of the ureters had broken loose from its new point of attachment, probably, as Mr. Stokes had suggested, through ulceration, due to defective blood-supply in the button of mucous membrane left around the end of the transplanted ureter. A pelvic abscess then formed which opened into the vagina, through which urine was thenceforward voided. The patient ultimately died three months after the operation from ascending pyelonephritis in both kidneys. The interest of the exhibit mainly lay in the relative rarity of this malformation in a female, and in the condition of the surviving ureteral papilla in the rectum. This was quite pervious, and apparently firmly attached, but was in a condition of superficial necrosis, all the transitional epithelium having perished with the exception of one tiny shred on its mucous surface, as shown in microscopic sections. This patient had passed for a boy until the date of the first operation, and neither she nor her people were ever disabused of this impression. She had a slight boyish figure, rather hairy arms and legs, and a deep-toned voice, but the total absence of circumoral hair and well-developed breasts of a woman.

Professor A. E. METTAM showed a specimen of Spontaneous Tuberculosis in a Rabbit.

Dr. J. H. POLLOCK showed specimens of Melanotic Tumour, Metastases in Lungs and Liver, and Portal Thrombosis and Cirrhosis in latter.

Dr. T. T. O'FARRELL showed a Stomach removed post mortem which exhibited two ulcers in the fundus and a carcinoma at the pylorus.

LIVERPOOL MEDICAL INSTITUTION.—A meeting of this society was held on March 9th, Major Charles J. Macalister, the President, being in the chair.—Mr. C. A. A. Dighton related a case of Sarcoma of the Nose and Naso-pharynx. The tumour was removed under chloroform in September, 1914. The operation performed was a sub-labial lateral rhinotomy, and in addition a wedge-shaped section of the upper jaw and palate was removed. The patient was shown. She was healthy and there had been no recurrence.—Dr. F. H. Barendt read an amusing and interesting paper on the Use, Misuse, and Abuse of Soap. He described the various pharmacopœial preparations of soap and discussed their relative value. In his opinion far too much soap was used, he said.—The President and Major Rushton Parker both joined in the discussion.—Captain T. R. W. Armour read an interesting paper on Military Orthopædics, in which he divided these cases into two groups: (1) Disabilities occurring in men under training, such as cases of flat feet, hallux rigidus and valgus, pes cavus, internal derangement of the knee, hysterical deformities of hip and spine, sprains, and old fractures; (2) cases due to wounds or other injuries received on active service. Captain Armour described a series of deformities produced by fractures of the femur, fractures involving the shoulder, elbow, wrist, and hand, injuries to muscles and nerves, and showed several radiographs illustrating the cases. The principles underlying the treatment of each case were discussed and progress described. Reference was made to the value of active exercises carried out under proper supervision as part of the treatment, and the necessity for getting the men to take intelligent interest in their own cases. Several points were brought forward with regard to the adaptability of stumps for the application of artificial limbs.—The paper was discussed by the President, Major Rushton Parker, Mr. G. P. Newbolt, Mr. F. A. G. Jeans, and Captain J. Lloyd Roberts.

LONDON DERMATOLOGICAL SOCIETY.—A meeting of this society was held at St. John's Hospital for Diseases of the Skin on March 21st, Dr. J. L. Bunch, the President, being in the chair.—The President showed, among other cases, a Belgian with a mixed large and small Follicular Syphilitic Eruption on the Trunk of three to four months' duration; the patient also had an atrophic scarring on the left eye, caused by a shell. A most successful transplantation had been performed in this region.—Dr. Morgan Dockrell showed a case of Idiopathic Multiple Hæmorrhagic Sarcoma which had greatly improved under thyroid extract and streptococcal vaccines. He also exhibited a case of Perforating Ulcer in a man who had received nine injections of salvarsan without any appreciable result. The condition was steadily improving under mercurial treatment.—Captain W. Griffith, R.A.M.C., showed a case of Pustular Folliculitis affecting the legs and thighs which had been treated by the Simpson light.—Dr. W. Knowsley Sibley showed, amongst other cases, a girl, aged 16, who had a rather unusual ulceration on the front of both legs, due to sitting before the fire.—Major E. G. Ffrench, R.A.M.C., showed a case of Strumoderma in a youth, the lesions occurring on the face and neck, which had been somewhat improved by applications of the Simpson light.—Captain C. H. Mills showed a case of Syphilis on an old-standing psoriasis. The patient also had a peculiar horny growth on the umbilicus.

MEDICAL MAGISTRATES.—Mr. Barclay Josiah Baron, M.B., C.M. Edin. (the Lord Mayor), and Mr. Colston Wintle, L.R.C.P., M.R.C.S. (chairman of the Health Committee), have been placed on the commission of the peace for the city of Bristol.

THE "STAR AND GARTER" HOME.—The following will act as the consulting staff at the "Star and Garter" Home for Totally Disabled Soldiers and Sailors:—Consulting physician, Sir David Ferrier, F.R.S.; visiting physician, Dr. S. A. Kinnier Wilson; consulting surgeon, Mr. Wilfred Trotter; consulting urologist, Mr. J. Thomson Walker; consulting ophthalmic surgeon, Dr. A. C. Hudson; honorary dentist, Mr. Donald Campbell; honorary surgeon, Mr. Harry Wade.

Reviews and Notices of Books.

The Treatment of Acute Infectious Diseases.

By FRANK SHERMAN MEARA, M.D., Ph.D., Professor of Therapeutics in the Cornell University Medical College in New York City, &c. New York: The Macmillan Company. 1916. Pp. 540. Price 15*s.* net.

IN regarding the group of infectious diseases from the point of view of the therapeutist we might endeavour to divide them into two classes—those for which some specific remedy has been discovered, and those for which none such has so far come to light, and in which, therefore, we are reduced to the practice of merely expectant or symptomatic treatment. We might again subdivide the former class into those, on the one hand, for which some recognised chemical compound or drug is efficacious, and those, on the other, for which some product of vital reaction is brought into play by the use of a serum or vaccine. Hitherto only malaria and syphilis appear susceptible to specific drug treatment, unless the use of emetine in dysentery or of the salicylates in rheumatic fever may be regarded as specific; while the list of diseases for which treatment by serum or vaccine is uniformly successful would narrow itself down to diphtheria, and perhaps tetanus, gonorrhœal septicæmia, and cerebro-spinal meningitis, to which must be added, if prophylaxis is classed as treatment, small-pox, enteric fever, and hydrophobia, and possibly plague and cholera, for all of which preventive vaccination has varying claims to our regard.

The book before us does not attempt any such classification but proceeds on ordinary lines, the diseases being merely arranged in the order which appeals to the author. The list includes rheumatic fever and leprosy, but not acute generalised tuberculosis or gonorrhœa or syphilis. The first two chapters deal with the symptoms of infection such as pyrexia and with the methods of combating them, and with the diet suitable to febrile conditions, which the author urges should be more liberal than is usually considered advisable, in order to make up for the wasting that accompanies toxæmia. He holds that after the first few days the digestive system resumes its activity and can deal with a considerable quantity of suitable food. Plenty of water is also called for. The diseases are then considered separately in full detail, the method involving a good deal of repetition, but being perhaps convenient for rapid reference. Among the advice given we note that the author is not in favour of the use of alcohol in febrile conditions—advice which is very usually founded rather on theory and prejudice than on observation of the effects produced by the drug. He speaks highly of the rectal administration of salicylates in rheumatism, and also of their employment by intravenous injection. He upholds the bath treatment of enteric fever, which has never made much progress in this country, but seems to be largely employed in the United States of America.

The fullness of the advice given as to the treatment of the various diseases should render this book acceptable to practitioners who are called upon to deal with them, and the counsel given is throughout sound and practical. Doses are given both in apothecaries' weights and measures and in the metrical system. A few mistakes are noticeable, as, for example, in placing vaccine treatment

of rheumatism under "complications" of that disease, and in the sentence (p. 500) "glowing accounts of vaccines (*sic*) have followed the use of Hiss' leucocytic extract," in which the word vaccines appears to take the place of some term such as "successes." There are few typographical errors, and the book is well got up and adequately indexed.

JOURNALS.

The Journal of Physiology. Edited by J. N. LANGLEY, Sc.D., F.R.S. Vol. L, No. 3. Cambridge: University Press. February, 1916. Pp. 157–216. Price 4*s*.—The Mechanism of Fluid Absorption from Tissue Spaces, by F. H. Scott. It is well known that the volume of the blood rapidly increases after hæmorrhage, which is due to the passage of fluid from the tissue spaces back into the blood capillaries. The change is rapid and cannot be accounted for by lymph flow. Indeed, it occurs after the thoracic duct is ligatured and after the intestines have been removed. Two theories have been put forward to explain this absorption of fluid: the backward-filtration theory of Landerer (1884) and the osmotic theory of Starling (1896). In the first theory it is assumed that when the pressure in the capillaries falls below that in the tissue spaces the fluid is forced back into the capillaries. According to Starling, there is normally a balance in the production and absorption of tissue fluid between the filtration pressure in the capillaries and the osmotic pressure of the colloids of the blood and tissue fluid. Plasma and tissue fluid are practically identical in their composition in everything except protein. The blood proteins exert an osmotic pressure of about 4 mm. of Hg for every 1 per cent. of protein. Since the plasma contains more protein than the tissue fluid its osmotic pressure is greater, and this greater osmotic pressure should cause an absorption of fluid when the capillary pressure is reduced. It seemed possible to the author that a comparison of the protein content of the blood before hæmorrhage and a short time after it might throw light on the nature of the fluid passing into the blood. The author determined the protein content of the fluid entering the blood-vessels after hæmorrhage in three cases in dogs. Experiments were also made in the blood of the living animal diluted with Ringer's fluid. The salt solution rapidly leaves the blood for the tissue spaces, so any backward filtration is excluded. The author finds that as large or larger increases in the nitrogenous bodies of the plasma occur after injecting Ringer's fluid (when all backward pressure is excluded) as occur after hæmorrhage. After hæmorrhage the fluid passing back into the blood must contain less protein than the plasma, whether it passes back by osmosis or by filtration; it will then necessarily cause protein to pass from the cells into the plasma. An increase of protein in the plasma after hæmorrhage is no evidence of backward filtration, and is consistent with Starling's view that the fluid passes into the capillaries by osmotic action. The author's results are grouped as follows: (1) After hæmorrhage an increase occurs in the total protein of the blood plasma, corresponding to a total protein content of 0·6 to 2·09 per cent. in the fluid which has passed through the capillary wall from the tissue spaces to the blood; (2) injection of Ringer's fluid into the blood leads to a similar increase of protein, even though the injected fluid is leaving the blood for the tissue spaces at a rapid rate; (3) the increase of protein occurring after hæmorrhage may then be attributed to the passage into the blood of fluid from the tissues containing little, and possibly no, protein. The increase is not inconsistent with Starling's theory that the increase in the volume of the blood occurring after hæmorrhage is due to the osmotic pressure of its proteins.—Glycolysis in Diabetic Blood, with a Method for the Estimation of Blood Sugar, by Hugh Maclean. According to the author, the problem of the action of diabetic tissues on glucose is still unsolved, and the question of excessive excretions of sugar in the urine in experimental and ordinary diabetes seems as obscure as ever. Conclusive experimental evidence that in diabetes the tissues have actually lost, either wholly or in part, the power to oxidise glucose is difficult to obtain. Perhaps the said power is by no means lost. Indeed, there does not appear to be any conclusive evidence at present that the diabetic organism as a whole is less able to destroy sugar than the normal one. Evidence is gradually accumulating which points to a lack of power to store sugar in a stable form as a more likely fundamental cause of glycosuria than an ability to oxidise sugar. The heart of a depancreatised dog originally was said to be unable to utilise glucose, and the same obtains in a diabetic heart perfused with Ringer's solution containing sugar. Later experiments show that the heart of the depancreatised dog destroys sugar, as evidenced by the diminished reducing power of the liquid after passing through the diabetic heart. The results of the study of the respiratory quotient point in the opposite direction and would appear to indicate that little or no sugar is destroyed. Normal human blood is known to destroy sugar when incubated at 37° C. There is, however, great difficulty in the accurate estimation of the sugar in small amounts of blood. The author gives a full account of his new method of estimating sugar in blood, for which we must refer the reader to the original. The author finds that there is no decrease of glycolytic power in diabetic blood; if the mechanism of sugar oxidation in the blood is similar to that in the tissues, it must be inferred that the diabetic tissues also possess the power to destroy sugar.—Studies in Calcium Metabolism: I. The Deposition of Lime Salts in the Integument of Decapod Crustacea, by J. H. Paul and T. S. Sharpe. A crab before "moulting" refuses food, lives a very inactive life, and seeks shelter. A crab—in the stage called "Pillans" on the North-East of England—denuded as far as possible of its hard shell, does not increase in size as it does when the animal leaves its shell naturally. The integument becomes more leathery, but calcium carbonate cannot be demonstrated in it. Certain internal conditions must obtain if the very rapid deposition of calcium carbonate is to proceed. Different animals, however, vary considerably in the rate of deposition of calcium. The general results may be summarised as follows: 1. After moulting there is a rapid deposition of calcium carbonate in the shell of decapod crustaceans. 2. In the edible crab calcium phosphate is present in the hepato-pancreas to the extent of about 20 per cent. of the bulk of the gland immediately before moulting. 3. After the shell has hardened this calcium salt is practically absent from the gland 4. The lobster does not store calcium in its gland as the edible crab does, but *Lithodes maia*, the stone crab, shows a slight storage. 5. Oil is present in the gland before moulting. It comprises from 20 to 50 per cent. of the total weight. When the shell has hardened it has almost disappeared, like the calcium salts. The iodine value is in inverse ratio to the quantity of oil and to the quantity of calcium. 6. The volume of blood is markedly increased immediately after moulting, even increased ten-fold. The total amount in circulation is greatly increased, although the percentage of calcium is practically constant. 7. Calcium is probably present in the blood as a salt of a fatty acid, and, since formic and butyric acids have been found to be present in combination with some base in the blood, they are to be regarded as the carriers of the metals. They are the members of the fatty acid group which most easily dissolve calcium salts.—Observations on the Nerve Endings, Receptive Substance and Contractile Substance of Muscle, by D. Noël Paton and Leonard Findlay. The conception that there is a "receptive substance," a peripheral neuromyal mechanism, a substance lying in proximity to the nerve ending, we owe to Langley. The action of curare on the muscles of the cat with nerve intact and then on recently denervated muscle was investigated. The authors think their results show that the "receptive substance" generally remains unaltered for some time after the nerve has ceased to act, and in this condition would give the results described by Langley with curare and nicotine. It is also possible that the "receptive substance" may in some cases have its excitability modified during the process of degeneration of the nerve, and the galvanic response characteristic of the reaction of degeneration may be the result of the degeneration of this substance.—The Cerebro-spinal Fluid. IV. Circulation, by W. E. Dixon and W. D. Halliburton. After epitomising their own work and that of other observers, the authors studied the effects of absorption from the cerebro-spinal fluid of various more or less easily detectable substances in the dog, and also absorption into the same fluid. Some experiments were made with dyes and pituitary extract. Amongst other results we note the following: 1. Substances introduced into the cerebro-spinal fluid appear rapidly in the blood and do not find exit by lymph channels. Readily

diffusible substances, especially if placed in the sub-cerebellar region, appear in the blood with remarkable speed. Adrenaline, nicotine, and atropine produce characteristic physiological effects almost as rapidly as if injected into the venous circulation. 2. Indiffusible substances—e.g., proteins—do not produce these characteristic effects when placed in the cerebro-spinal fluid. Secretin—of intermediate molecular size—diffuses slowly. The diffusion process is most rapid in the sub-cerebellar region and extremely slow in the lower spinal area. 3. The authors hold that it is by the blood and not by the lymph that the fluid which is constantly being secreted finds its main exit from the cranio-vertebral cavity. 4. Some evidence is presented that dyes—methylene blue, carmine, granular Indian ink, potassium ferrocyanide, and iron ammonium citrate, the tissues being subsequently treated with hydrochloric acid—added to the cerebro-spinal fluid, travel along the course of certain cranial nerves, especially the olfactory nerve. In the spinal nerves no dye can be detected in the sheaths outside the spinal cord, nor was dye found in the lymph of the thoracic duct. 5. Diffusion from blood to cerebro-spinal fluid does not occur except in an almost negligible degree with a few drugs—e.g., urotropine. The secreting epithelium of the choroid gland protects the tissue elements of the central nervous system from being bathed with harmful substances. 6. Pituitary extract has no direct action on the secretory activity of the choroid gland. Statements to the opposite effect can be explained by the non-exclusion of an asphyxial condition due to constriction of the bronchioles, which is a powerful stimulus to cerebro-spinal secretion.

ROYAL MEDICAL BENEVOLENT FUND.

AT the last meeting of the committee held in March, 26 cases were considered and £207 granted to 20 of the applicants. The following is a summary of the cases relieved:—

Widow, aged 46, of M.R.C.P. Irel. who practised at Norwich and died in January, 1916. Applicant left totally unprovided for with four children, aged 5 to 19. The eldest has joined the army and the youngest are at school. Applicant's health is bad, and she has no friends. Voted an immediate grant of £5, pending further inquiries.—Daughter, aged 44, of M.D. Edin. who practised at Leamington and died in 1884. Applicant along with her mother managed, with the aid of the Fund, to get along by letting some of their rooms. The mother died recently, and the applicant was unable to manage without a little help. Voted £6.—Widow aged 68, of M.B. Edin. who practised at Bolton and died in 1905. Applicant lost about £700 through a defaulting trustee, since dead, and her only certain income is £10 per year. One daughter, a shop assistant, lives at home and helps as much as she can. Voted £12 in 12 instalments.—Widow, aged 62, of L.R.C.P. Irel. who practised in North London and died in February, 1916. Her late husband was a pensioner both of the Fund and Epsom College. Applicant has no income, and at her age expects it will be difficult to find work. Voted £12 in 12 instalments and referred to the Guild.—Widow, aged 61, of L.R.C.P. Irel. who practised at Mitcham and died in 1914 after a long illness during which all his savings were spent. Applicant is now practically dependent on the hospitality of friends. Relieved three times, £40. Voted £10.—Wife, aged 37, of M.R.C.S. Eng., is in an advanced state of tuberculosis, and her husband is in an asylum. There are three children; the eldest is being cared for by a relative, the second is in an orphanage, and the youngest living with the mother. Relieved once, £18. Voted £18 in 12 instalments, and referred to the Guild.—Daughter, aged 39, of L.R.C.P. Edin. who practised at Earlsfield and died in 1902. Applicant is blind, and is training as a masseuse. Prior to the recent death of her mother, who had a pension for life, they managed. The applicant is now dependent on a relative who has to earn her living. Help wanted for tuition fees. Voted £10.—Daughter, aged 66, of M.R.C.S. Eng. who practised at Plymstock and died in 1879. Applicant has recently lost £30 per annum through the death of a friend. Only certain income £11 per year. Lives with sister, who receives an annuity from the Fund. Relieved three times, £35. Voted £12 in 12 instalments.—Daughter, aged 55, of M.R.C.S. Eng. who practised at Manchester and died in 1898. Applicant managed to earn her own living until an attack of nervous debility a few years ago necessitated her giving up her work. Only income a pension from her late employer of 6s. per week. Relieved twice, £24. Voted £12 in 12 instalments.—Daughter, aged 49, of M.D. Glasg. who practised in Derbyshire and died in 1872. Applicant was left totally unprovided for, and has tried to earn a living by taking in paying guests, but owing to the war has not been successful of late. Relieved once, £10. Voted £10 in two instalments.—Widow, aged 61, of L.R.C.P. Edin. who practised at Dumfries and died in 1908. Was left unprovided for with four children, none of whom are able to help. Only income a pension of £12 per annum from another society. Relieved seven times, £68. Voted £12 in 12 instalments.—Widow, aged 58, of M.D. Edin. who practised in Cumberland and died in 1903. Left totally unprovided for, and tries to earn a living by taking in boarders, but owing to her residence being on the East Coast has been unsuccessful since the war. Has four children, all married and unable to help. Relieved 10 times, £112. Voted £12 in 12 instalments.—Daughter, aged 52, of M.R.C.S. Eng. who practised in London and died in 1895. Owing to exceedingly bad health applicant is unable to take permanent employment. Only income £28 per year. Relieved four times, £51. Voted £12 in 12 instalments.—Widow, aged 47, of M.D. Edin. who practised in Glasgow and died in 1912. Applicant was left unprovided for with seven children. The elder ones are now married and unable to help, and the four younger children are at school. Only permanent income £22 from other charities. Tries to supplement this by taking in boarders, but unsuccessfully. Relieved four times, £72. Voted £20 in 12 instalments.—Daughter, aged 65, of M.R.C.S. Eng. who practised in London and died in 1853. Left totally unprovided for, and has worked in various ways to try to support herself, but was unable to provide for her old age. Her income now from a charity and friends totals £28, and she tries to supplement this by poultry-keeping. Relieved three times, £30. Voted £6 in 12 instalments.—Daughter, aged 67, of M.R.C.S. Eng. who practised in North Devon and died in 1903. Was left totally unprovided for, and her health is exceedingly unsatisfactory, which has prevented her from working. Her only income has been a few shillings weekly from friends. Previous help £14. Voted £12 in 12 instalments.—Widow, aged 46, of L.S.A. Lond. who acted as ship's surgeon and died in 1912. Was left with three children, aged 8 to 24. The eldest is unable to assist, and the others are too young to do anything. Applicant is now working as a typist at £1 per week, but finds it insufficient to keep four persons. Relieved four times, £18. Voted £12 in 12 instalments and referred to the Guild.—Widow, aged 66, of Surgeon in the Army Medical Service who died in 1888. Only income a War Office pension. Was operated upon six years ago for cancer, and had breast removed. Has four children, but all married and none able to help. Wants a little help to furnish spare bedroom so that she might take in a paying guest. Relieved once, £16. Voted £5 through the Guild.

Subscriptions may be sent to the honorary treasurer, Dr. Samuel West, 11, Chandos-street, Cavendish-square, London, W.

New Inventions.

EXTENSION GLOVE FOR CASES OF MUSCULO-SPIRAL PARALYSIS.

THE glove here illustrated is designed to replace the paralysed extensor muscles, maintaining the extended position of the hand and fingers, and the relaxation of those muscles which is essential to their recovery. A leather armlet above the elbow is connected by an adjustable leather strap to the wrist of a stout leather glove. Inside the glove elastic bands pass from the wrist to the top of each finger. These bands pass through wash-leather loops which maintain them in position, and they are so adjusted in tension as to just maintain the extension of the fingers. The effect of the whole is that when the flexor muscles are relaxed and the hand is at rest the fingers are completely extended and the

wrist is slightly dorsiflexed. On contraction of the flexor muscles the fingers and wrist can be flexed and the hand used in an almost normal manner. An important feature is the increase in power of grasp produced by the extension of the wrist. The glove has great advantages over any form of fixed apparatus, for it allows perfectly free movement of every joint and does not interfere with the balance in walking.

The glove is quite inexpensive, and is made by Messrs. Allen and Hanburys, Limited, 48, Wigmore-street, W.

H. S. SOUTTAR, M.B., M.Ch. Oxon., F.R.C.S. Eng.
Queen Anne-street, W.

THE STANLEY HOSPITAL, LIVERPOOL.—At the annual meeting of supporters of this hospital, held on April 3rd at the Town Hall, the Lord Mayor of Liverpool, who presided, said that the past year had been one of exceptional difficulty. Some 60 beds had been placed at the disposal of the Government for wounded and sick soldiers and sailors, and the appreciation expressed by those treated had been most encouraging and gratifying. To meet the increased expenses in all directions he earnestly appealed for £1500. The number of cases treated in the hospital for the past year was 15,075, including 1078 in-patients, among whom were 323 wounded soldiers.

THE LANCET.

LONDON: SATURDAY, APRIL 8, 1916.

The Health of Munition Workers.

IT will be remembered that last year a Committee was appointed with the concurrence of the Home Secretary and under the chairmanship of Sir GEORGE NEWMAN, the principal medical officer to the Board of Education, with the following reference:—"To consider and advise on questions of industrial fatigue, hours of labour, and other matters affecting the personal health and physical efficiency of workers in munitions factories and workshops." This Committee has already made a number of valuable reports to the Ministry of Munitions, and the last four Memoranda[1] are of the first practical importance at the present moment. Munitions are being produced at high pressure, and the Memoranda suggest how, without lessening our output of guns, of shells, and of other appliances of war, we may obtain a supply equal to our needs with greater economy of life and health of our fellow-citizens of both sexes. The inquiries of the Committee are not directed to these subjects only in connexion with the war, nor has its advice an application limited to the munition workers for whose benefit it is promulgated as a matter of urgency. Commercial industry will have to be organised with energy, and factories will continue to be worked at full pressure when war is over, if we are to maintain our national position in the world's markets; and the Committee points out that, to the detriment of both health and wealth, the management of our factories has hitherto been less based upon experimental science than has been the case in the business concerns of Germany, the enemy whose industrial organisation and energy are now standing her in such good stead.

In the Memorandum VII. upon industrial fatigue, the Committee expresses the hope that the study of this subject, now forced into notice by immediate need, may have results that will benefit the industries of the country during coming years of peace. One impression produced by this Memorandum is that in these days of stress we are paying dearly now for errors committed in the past, and for recklessness in regard to health permitted in the nineteenth century under conditions of plentiful labour and industrial expansion. The scientific and physiological aspects of fatigue described in this Memorandum might well have been realised in times of peace, and we ought not to have had to wait until the war arrived for the outlining of practical remedies and the regulation of hours of labour, so that the health of the worker might be conserved and the fruits of his toil increased. Certain industrial undertakings, arising out of the war, have special problems of their own—for example, the risks entailed by exposure to lead, tetrachlorethane, nitrous gases, and nitro explosives. In Memorandum VIII. dealing with special industrial diseases, the Committee usefully draws attention to the existing regulations established by the Home Office in 1901 in regard to the risks of contact with lead, but it does not appear that the handling of bullets gives rise to serious lead poisoning. The symptoms of poisoning due to tri-nitro-toluol (T.N.T.) are described and measures for minimising the risk are outlined. Similarly the eczema arising from contact with tetryl, or tetra-nitro-methyl-aniline, is referred to, and here again protective measures are suggested. The Committee refers to the various leaflets and memoranda, dealing in greater detail with industrial diseases and their prevention, and issued by the Factory Department of the Home Office, and in many directions they have relied upon the assistance of Dr. T. M. LEGGE, the senior medical inspector at the Home Office, whose wide experience has been of the greatest value. In Memorandum IX., which discusses ventilation and lighting, the Committee sets out considerations and suggestions which, it hopes, may prove of assistance to those responsible for the ventilating, heating, and lighting of old factories, and for the planning of new factories and workshops. In Memorandum X. it inculcates the importance of two cardinal principles:—that the prevention of disease is better than waiting till it has to be cured; and that treatment to be effective must deal with disease at its beginning, steps being taken to secure recognition of its presence at an early stage.

The urgency of the demand for increased supplies to our armies in the field has been the cause of the evils which have arisen, and it is recognised that injury to the health of munition workers, where it has occurred, has been largely due to their own patriotic zeal. The Committee has rightly laid stress upon the increase or diminution of output as the most direct test with regard to fatigue, and in explaining this has been careful to supply examples from actual experience, which are likely to appeal more directly to many laymen than explanations of the causation of fatigue from the point of view of the physiologist. Excessive fatigue due to overdriving the human machine is thus placed in its true light, not as a hardship which must be endured by the worker for the sake of the cause in which he is sacrificing his comfort or his health, but as an enemy, to him and to the country, which must be guarded against, because it diminishes production and because any loss of health due to it is a useless and wasteful extravagance. Moreover, the Committee recommends that proper management should take account of the output of particular individuals, and explains that where this has been done variations of individual output have been discovered which have been independent of personal willingness and industry. Two good results thus ensue: it has been possible to detect in individual workers superiority of method, obtaining from their example valuable hints for the instruction of others, and

[1] Memorandum VII., Industrial Fatigue and its Causes. Cd. 8213. VIII., Special Industrial Diseases. Cd. 8214. IX., Ventilating and Lighting of Munition Factories and Workshops. Cd. 8215. X., Sickness and Injury. Cd. 8216. Obtainable from the usual official publishers, or through any bookseller.

also to impose upon each the work best suited to his powers, rearranging and assigning the work in such a way as to secure its most effective performance. In matters appertaining to health, the desirability of watching for early signs of breakdown is insisted upon; in this way only can it be dealt with promptly, so that the worker may return with the least possible loss of time. With regard to accidental injury, explicit instruction is given as to both the institution in a factory of a local dressing station for minor injuries and a central dressing station or surgery for the treatment of more serious cases; the actual treatment which should be accorded in the absence of surgical assistance is also mentioned. A leaflet issued by the Home Office is appended here, containing explanations of a practical character as to what should be done and (of equal importance) as to what should not be done by the injured worker and those in his immediate neighbourhood in order to avoid sepsis and the conversion of a slight hurt into a serious one. In the matter of ventilation and lighting, with the cognate topic of heating, the Committee has recognised the fact that the problems to be dealt with must depend largely upon the particular circumstances of each case, and has set out considerations and suggestions in the hope that they may prove of assistance. The essentials of good lighting are summarised and means are proposed to secure its adequacy, with uniformity of illumination, with protection for the eyes of the worker, and with the avoidance of unnecessary shadows upon the work. Fortunately, as the period of daylight is now increasing, and summer draws near, questions of lighting and heating workshops and factories will become for a time easier of solution, but a considerable amount of night-work will still have to be done, and both by day and night bad lighting has as its results headache and other effects of eyestrain, as well as a diminished output. Ventilation, we are inclined to think, is a more difficult problem for the factory manager to deal with than even lighting, although it, too, becomes easier in warm weather than in winter. The Committee insists upon the necessity for a stimulating as well as a clean atmosphere for workers, but the stimulation of moving air is perhaps not unnaturally liable to be resisted by the workers when the breeze is introduced from outside at a temperature many degrees lower than the interior where they are congregated.

May we express the hope that the weighty precepts which the Committee desires to inculcate will win intelligent appreciation beyond the limits of Mr. LLOYD GEORGE'S jurisdiction as Minister of Munitions? If we leave out the passages referring to accidental injuries, there is little in the Memoranda upon which we have commented which might not be applied with equal force where work is being done in offices under various other departments in connexion with the war. A large host of clerks, typists, and other sedentary workers of both sexes is being employed, and has been ever since the war broke out, in operations which require unremitting attention, and for spells which have no parallel for similar occupations in time of peace. For these men and women unduly long hours, lack of weekly and other holidays, excessive night-work, bad lighting, and bad ventilation are no less to be deprecated than for the more laboriously occupied munition worker. And the result must always be the same with all classes of workers—injury to health, temporary or permanent according to circumstances, so far as the individual is concerned, and as far as the public is concerned diminished efficiency, retarded production, and waste of money in paying for that which affords no adequate return.

The Supply of Medical Men for the Navy and Army.

THE War Office, in a statement which is also an appeal, declares that, in order to maintain the supply of medical officers needed in the military services, it is necessary that all qualified medical men up to 45 years of age should fall in with the Enrolment Scheme of the Central Medical War Committee. The statement of the War Office on the subject is published in full in THE LANCET this week, and has, we are glad to say, also received very wide notice in the lay press, its public issue being dictated by the fact that urgency is as much necessary in the interest of the civil community as it is in that of our armies. It is thus made perfectly clear that in the opinion of the military authorities there is only one way, unless new regulations are made, to obtain a sufficiently large body from which to choose those who should enter upon military service and those who should remain in civilian employment; and this way is a very general enrolment. Nor must it be forgotten that the navy also needs medical officers, and that this need may become acuter. The navy has refrained from making any claims upon the civilian profession recently, but its right to whatever it requires is paramount.

The War Office points out that enrolment, the machinery of which is already being conducted by three representative bodies for England and Wales, for Scotland, and for Ireland respectively, does not imply that the enrolled medical man will be at once called up for service in the Royal Army Medical Corps; this we have stated on several occasions, and we are glad to read the official endorsement. As a matter of fact, the enrolled man may never be called up, and in any case will not be requisitioned until the proper time for his services to be accepted has arrived; and that time will be ascertained by a careful consideration of all the circumstances concerning his practice and the practices of his immediate colleagues, as well as the medical provision for the community which, in the time of peace, he serves. It is in this way that the Enrolment Scheme should lead to those medical men being selected for the services who can best be spared by a particular date and from a particular place, a properly proportioned regard being paid to the needs of the three parties concerned, the fighting organisation, the civil population, and the medical officer. We hope, indeed we expect, that the clear words of the War Office will remove some of the doubts which have been

experienced by the members of the medical profession, both as to the need for additional medical men in the Royal Army Medical Corps and the practicability of the method chosen by the Central Medical War Committee for meeting that need. The Enrolment Scheme, if entered into by a large majority of the constituency concerned, should ensure an equitable distribution of the burden as it affects the medical profession; and in order to avoid the alternatives of haphazard recruitment or arbitrary demand, the War Office has officially decided to rely upon the Central Medical War Committee, and the corresponding Committees in Scotland and Ireland, to meet the shortage in the Royal Army Medical Corps as it occurs. The extent of that shortage is not suggested, in so many words, by either the navy or the army; but it is clear that it must depend upon the course of the war and the rapidity with which additions are made to our fighting formations.

The Central Medical War Committee has been subjected to an extraordinary amount of criticism. Distrust of its policy, its actions, and indeed of its morals, has been widely suggested, and the number of times is very great that questions have been asked in Parliament having as their aim the extraction from the Government of some admission that may be damaging to the status of the Committee. As far as can be ascertained, the Committee has worked steadily for the good alike of the medical profession and the community. We are glad, therefore, to see the Committee and its Scottish and Irish similars described in the War Office statement in the following terms:—

> These Committees include representatives of the Royal Colleges of Physicians and the Royal Colleges of Surgeons, of the Universities and Medical Schools, and of the British Medical Association, and have associated with themselves in their work representatives of the Government Departments mainly concerned. The Committees have an organisation of representative local committees in all parts of the three countries, from which they obtain local information and advice, and they work in daily contact with the various Government Departments concerned. Furthermore, for the purpose of considering and advising, through the Central Committee, on cases in England and Wales having such special features as exist, for instance, in regard to the staffs of the metropolitan hospitals, a Committee of Reference has, with the approval of the War Office, been now established by the Royal College of Physicians of London and the Royal College of Surgeons of England, acting jointly.

May we hope now that all medical men will work to assist the Central Medical War Committee in promoting the Enrolment Scheme and in finding the fittest civilian medical men to serve in the navy and army? The Enrolment Scheme becomes an essentially fair one, seeing that the Central Medical War Committee has decided to call up no practitioners under it unless and until 75 per cent. of those medical men, who on Jan. 5th, 1916, were of military age, have enrolled or received a commission.

THE LATE MR. W. B. RICHARDSON.—William B. Richardson, late senior surgeon to the Victoria Hospital, Blackpool, died suddenly on March 30th, in his sixty-ninth year. He became a Member of the Royal College of Surgeons of England in 1875, and had been in practice for 40 years in Blackpool. He was one of the founders of the Victoria Hospital and generously supported that institution, of which he was honorary surgeon for 20 years.

Annotations.

"Ne quid nimis."

THE BUDGET AND THE MEDICAL PROFESSION.

THE Fourth War Budget is of the colossal magnitude which was to be expected in view of all the circumstances, and in its main features it is so clear that we may take it for granted that our readers are already acquainted with their main purport. It is doubtful if it was generally expected that the income-tax would be raised in quite the manner employed or to such high figures; but the announcement that there is to be no increase in this respect on naval and military pay will be a welcome relief to the large numbers of our profession who are doing their duty with the forces, The rest of us will bear the graduated increases, which range from 5*d.* in the £ on incomes above £500 and under £1000 to 11*d.* on incomes under £2000, with that cheerfulness with which medical men usually shoulder their share of the responsibilities of citizenship. The increases on incomes between £2000 and £2500, which are more onerous, do not affect a large proportion of our unwealthy class. Those who are so fortunate as to possess unearned incomes will have to pay an addition of 6*d.* in the £ on incomes between £500 and £1000, and of 1*s.* in the £ on incomes above this sum and below £2000. The new proposals for taxation introduce some features of particular importance to the medical profession. The raising of the licence duty on motor-cars will affect the practitioner in proportion to the horse-power of his car. It will fall more heavily on the owners of American cars, and especially on those who have the "Ford" car, the duty on which is raised from £6 6*s.* to £18 18*s.* This represents a serious difference in annual outlay to a man whose practice is not a large one, and indeed the doctor is being hard hit at the present time in connexion with his motor-car, which he cannot put down as it has become indispensable to him in the working not only of his own practice but quite possibly of the practice of an absent colleague. The precarious supply of his petrol is a source of perpetual worry, he has to pay an exorbitant price for it when he does get it, and now he has to pay double or treble the licence duty. We feel that before the Budget proposals pass into law an effort might fairly be made to give the medical man some relief.

THE SUPPLY OF PETROL TO MEDICAL MEN.

THE form issued to medical men at the end of last week by the National Health Insurance Commission, asking them to supply details concerning their use of motor vehicles and their consumption of petrol, is a welcome sign that our authorities are alive to the urgent necessity for securing to practitioners an adequate supply of motor spirit. If some such course is not taken it may become impossible for some medical men to carry out their professional duties with that expedition which their calling and their attenuated numbers demand. For it must be remembered that several thousands of our colleagues are away from their practices and that the shortage of medical men with the services is still unsatisfied. Complaints have reached us already of the serious position in which some medical men find themselves in consequence of their inability to get petrol, especially in

remote country places. That there would be a sufficiency of spirit for the Government purposes and yet leave an ample supply to meet the real necessities of the public appears to be generally agreed if "pleasure" motoring is put down; the use of petrol, for instance, in conveying the votaries of horse-racing to and from their places of meeting is simply a scandalous waste—that such a thing should be permitted reduces our allies to complete bewilderment and seems to more thoughtful citizens to render the Zeppelin raids, with their attendant horrors, a tonic to be taken gratefully. Given an adequate supply of petrol, the great difficulties to be overcome are, of course, those of proper transport and distribution. There is little doubt that a restriction will soon be put upon the present indiscriminate use of the spirit, but the medical man, who is generally allowed to be among those who would have first claim upon the supply, will unfairly suffer under such a system. A regularised supply will not avail the practitioner in the remote and smaller country villages unless some means are evolved by which he can get without fail that amount of petrol which will enable him to carry on his work. There would appear to be only one way in which the regular supply of petrol to the medical profession can be secured, and that is by the Government taking over the whole of the petrol supply of this country, and using the existing organisations of the two or three great supply companies for its distribution. Otherwise it seems clear to us that many medical practitioners in the country may have infinite anxiety and may be forced to curtail their range of work in a disastrous manner. The supply companies know the requirements of the districts, including every little village and hamlet; and there would be no need for the work of the medical man to be crippled if their services were properly acquired. The question has become acute in some places, and no doubt much more acute than it need have been at the present time owing to the action of many car owners who, having bought largely in view of a threatened famine, hold up not merely the spirit itself, but, what is of even more importance, the tins in which the spirit is stored. Another point to which the authorities should give their attention is the exorbitant price which is now being charged for the commodity. Is this governed by ordinary commercial considerations, or by the demands of the oil trusts? To the medical man the successive increases in prices during the past few months are a very serious charge on his income.

THE DISINFECTION OF SEPTIC JOINTS.

Dr. F. J. Cotton has contributed to the *Boston Medical and Surgical Journal* an important paper on a subject of considerable interest at the present time—the disinfection of septic joints. He strongly condemns the drainage of joints as responsible for the disastrous results obtained in the past in cases of suppuration. Either the attempt to save the joint should be regarded as hopeless, in which case the joint should be laid wide open (not drained), or all efforts should be made to preserve the function of the joint. About 10 years ago, when engaged in washing out gonococcic joints, Dr. Cotton found, both in the small minority which gave a culture and the majority which did not, that the results were better if the joint was sewed up tightly than if it were left to drain through loose suturing, while wick or tube drainage proved, as has since been recognised, disastrous to function. He then treated septic joints (principally staphylococcic with a few streptococcic) by sewing up the capsule tight after irrigation for 15 minutes with a full stream of 1 in 15,000 corrosive sublimate and flushing out the excess with saline solution. He effected water-tight closure of the capsule by mattress and single sutures in such a way as to leave the synovial membrane cut-edge to cut-edge as accurately as possible. Usually the membrane is so swollen as to make this possible. The external wound is left wide open or nearly so, for complete disinfection of the external soft tissues is not practicable. After operation effusion into the joint may or may not occur. If it does, it disappears in one to three days and is not accompanied by pyrexia or much discomfort. With few exceptions, Dr. Cotton has not found traction for the separation of joint surfaces necessary. There was neither pain nor spasm sufficient to indicate it. In about two dozen cases treated by this method there were only two failures. In a case of streptococcic infection of the knee in a man, due to a punctured wound, recurrence took place. The joint was then laid wide open. Later, after vaccine treatment, the granulations were cleaned out from nearly intact cartilage and the divided ligaments were sutured. In the end the patient regained a good leg with 45 to 50 degrees of motion. In the other case a boy had an epiphyseal staphylococcic infection of the knee. The joint was cleaned out and sutured. Later the joint broke down and ankylosis resulted. The following shows the usual result. A sturdy girl aged 10 years was seen in consultation. About two weeks previously she hurt her knee in jumping down a cellar. The knee was greatly distended, tender and hot, but not red. The temperature was 102·5° F. A juxta-epiphyseal infection of the knee was diagnosed. The joint was opened on the inner side and found full of thick creamy pus. The irrigation described above was performed and the joint closed. Through an incision on the outer side a large popliteal abscess was opened and drained. After eight days there was no fluid in the joint, the tenderness was less, and the wound had nearly healed. Though a sequestrum formed in connexion with the epiphyseal line of the femur and a sinus at this spot persisted for a year, the knee-joint so completely recovered that it could be distinguished from the other only by the scars.

AMBARD'S COEFFICIENT.

THE index of urea excretion known as Ambard's coefficient or constant and enunciated by him in 1911 is perhaps less appreciated in this country than on the continent and in America. The formula devised by Ambard may be expressed as— $\frac{Ur}{\sqrt{\frac{D}{W}}\sqrt{C}} = K$, where Ur represents grammes of urea per litre of blood, D the grammes of urea excreted in 24 hours, W the weight of the patient in kilogrammes, C the grammes of urea per litre of urine, and K the coefficient or index of urea excretion. Dr. V. Grossi has lately made some observations on the clinical application of this coefficient which are published in *Il Policlinico* (Surgical Section, Feb. 15th, 1916), the cases consisting of 13 renal tubercle, 9 hæmatogenous infections, 8 calculous pyelitis, 3 renal growths, and 8 surgical affections of the lower urinary tracts. The conclusions arrived at by Dr. Grossi are that Ambard's coefficient is a valuable method for ascertaining the efficiency of the renal function, and is

capable of confirming in its extreme limits a fatal prognosis or of advocating caution as to operative intervention. It is superior to colorimetric methods in cases where ureteric catheterisation is impossible. The interpretation of the coefficient must be made in each case based on its various factors, and must not be taken as an absolute number. The significance and pathology of uræmia and of Ambard's coefficient are far from being clear; in the present-day state of our knowledge they must be regarded as ordinary signs which merit great importance and extended application similar to the presence of albumin in the urine.

THE CORTICAL REPRESENTATION OF MACULAR AND PANORAMIC VISION.

THE last number of *Brain* (December, 1915) contains a valuable contribution to the study of the complexities of the cortical representation of vision, in which Dr. Byrom Bramwell, of Edinburgh, Professor J. Shaw Bolton, of Leeds, and Dr. William Robinson, of the West Riding Asylum, Wakefield, have collaborated. The case is that of a man who was seen originally by Dr. Bramwell as long ago as February, 1886, when the patient was 45 years old. His complaint was loss of vision, which was said to have come on suddenly with an attack of what appeared to be uræmic convulsions in June, 1884. On examination the loss was found to consist in complete abolition of peripheral vision, with very marked reduction of macular vision. Dr. Bramwell saw the patient at regular intervals up to his death from pneumonia on Oct. 21st, 1910. During 24 years the condition remained practically speaking unchanged; macular vision improved slightly, while peripheral vision remained completely obliterated. Throughout the whole course of the case there was no motor paralysis, loss of sensibility, or any form of aphasia. Some five years before the patient's death his ocular condition was independently examined by Dr. A. H. H. Sinclair, of Edinburgh, who reported extreme contraction of the visual fields, the fixation point being probably encroached upon on the left side in both eyes: R. V. = 6/36 uncertainly; L. V. = 6/36 and 6/24 partly. The pupils were equal and reacted to light. Both optic discs had a somewhat leaden-grey atrophic appearance, with extensive shallow cupping. The brain lesions were eventually found to consist in extensive destruction of the white matter and part of the cortex of the left occipital lobe and also of the right occipital lobe, apparently the result of old embolic softenings. The pathological investigation was exhaustively worked out by Professor Shaw Bolton and Dr. Robinson. On the right side the lesion, which was mainly on the outer aspect of the lobe, reached the occipital pole and nearly to the outer extremity of the calcarine fissure; nowhere else in either hemisphere did the lesion come into even the approximate neighbourhood of the cortical visuo-sensory area. The cortical extent of the latter was delimited on both sides by laborious histological methods, and ascertained to be more or less strictly normal in distribution—i.e., embracing the calcarine fissure and its immediate vicinity. Pathologically speaking, no defect was discoverable in the cortex of the calcarine fissure and that quite adjacent to it, whereas the cortex of the whole peripheral portion of the visuo-sensory area was the seat of a simple atrophy involving mainly the three outer layers of the grey matter. The surrounding visuo-psychic cortex exhibited little or no abnormality. The conclusions drawn from this case are that the calcarine core of the pear-shaped visuo-sensory area serves as an anatomical basis for macular or central as distinct from non-macular, peripheral, or panoramic vision, while the latter is represented in the surrounding and remaining visuo-sensory cortex. It is probable that human macular vision is an evolution dependent on the development of the faculty of using corresponding parts of the retinæ simultaneously, and that it is superposed on the neuronic apparatus for panoramic vision, the two types shading into one another. The writers of this paper are to be congratulated on the patience with which they have followed up and investigated so striking a case.

NITROGEN: ITS VIRTUES AND ITS VICES.

PERSONS who talk of the importance of chemistry in this war are usually talking of one thing only, though they may not know it—and that thing is nitrogen. The chief chemistry of the war is practically centred on nitrogen. Recognising this fact, it is strange to think that we live by breathing an atmosphere containing 80 per cent. of this element which in certain combinations is dealing out death on an appalling scale in all the fields of action. There are practically no useful explosives employed in which the action of nitrogen is not concerned. Without its aid the great ships at sea could not be sunk, or innocent victims on land killed, or property destroyed by the aeroplane and dirigible; while it serves to mow down whole columns of men in the field, for rifles, howitzers, machine-guns, and grenades are all dependent upon, and made terribly deadly by, the offices of nitrogen. We every day pass on to our lungs something like 450 gallons of nitrogen per 24 hours, which would be enough to make 30 pounds of tri-nitro-toluol, or 40 pounds of gun-cotton. In our early training in the elements of chemistry we were wont to regard nitrogen as a singularly uninteresting gas on account of its negative behaviour. It did not burn like hydrogen, it did not support combustion like oxygen, and, in short, its presence was generally assumed because of its inactivity and because it did not directly respond to any test. And yet this element is the greatest of all as a munition power; it is hardly an exaggeration to say that applied nitrogen is going to be a factor in deciding the issue of the war. It is remarkable, also, that this element forms the central figure in the protein group or tissue-repairing material of our foods. To say that without protein we die, practically means that without nitrogen we die. The gas without positive tests is as necessary in one form for our support as in other forms it is ready to destroy us. Nitrogen's power depends in the first place on the fact that it carries in oxygen to compounds which are thus rendered explosive, turning all the elements into a huge volume of gas, itself being set free. The very inertness of nitrogen, or its objection to affinity, means that on the least provocation it will easily release its partner oxygen, handing this over to the combustion of other elements present, with the formation of volumes of gases, the nitrogen returning to what is apparently its congenial condition, the free state. As a fertiliser in the soil nitrogen acts as a stimulant and supplies the necessary nitrogen to the plant. In other words, it is a plant food. Thus the remarkable thing about nitrogen above all other elements is its power to destroy life or to sustain it according to the associates with which it is in company. With

certain accomplices it forms death-dealing explosives, with others it become a nutritive material. It is the essentially romantic element, devil or god, according to its associations.

THE TREATMENT OF LEPROSY BY CHAULMOOGRA OIL.

WE have on a previous occasion discussed in these columns[1] the treatment of leprosy by chaulmoogra oil, a remedy which is one of the few to retain a reputation after an extended trial in what is regarded by many writers as a hopeless disease. In a recently published special bulletin of the United States Public Health Service[2] entitled "Studies upon Leprosy," Dr. George W. McCoy, director of the U.S. Leprosy Investigation Station, Hawaii, and Dr. Harry T. Hollmann contribute an article giving a summary of the state of our present knowledge of the treatment of leprosy by chaulmoogra oil. These observers, in view of the interest which has been displayed of late on the subject, were led to review the current literature and to place on record their results with this remedy in the Hawaiian Islands. Most of the writers on the employment of this oil in the treatment of leprosy, including, among others, Manson, Scheube, Castellani and Chalmers, Morrow, Hutchinson, Sandes, Ashburton Thompson, and Dyer, express opinions more or less favourable concerning it. The theory of its action seems to be that it increases the number of leucocytes, and that it also increases the bactericidal properties of the blood. Some of its derivatives have been employed, notably the gynocardate of magnesium, which was used many years ago by Dr. Phineas Abraham. In THE LANCET of Feb. 5th Sir Leonard Rogers published a Preliminary Note on the Use of Gynocardates Orally and Hypodermically in Leprosy, in which he stated that he had obtained improvement both in anæsthetic and in tubercular cases more rapidly under the influence of hypodermic injections of sodium and potassium gynocardates than under any other treatment he had tried, including nastin, as also chaulmoogra oil and gynocardic acid by the mouth. He therefore urged others to give this method a careful trial. Referring to the pain produced by the hypodermic injections, he attributed this to palmitic acid present as an impurity, but we have been assured by Mr. W. H. Martindale that palmitic acid is one of the natural constituents of chaulmoogra oil, so that it cannot be regarded as an impurity, though different samples may vary in the amount of this acid that they contain. Mr. Martindale, while recognising Sir Leonard Rogers's high authority, doubts whether the presence of palmitate is the cause of pain complained of. Mr. Martindale has divided the mixture of acids obtained from genuine chaulmoogra oil into two fractions which he has converted into the corresponding soda salts termed respectively sodium chaulmoograte "A" and sodium chaulmoograte "C." The "A" salt contains true chaulmoogric acid plus palmitic acid and other acids of high melting points, while the "C" salt contains the acids of low melting points. The "A" represents from 50 to 75 per cent. of the total "chaulmoogric acid" of commerce, the "C" constitutes the rest. This "A" salt is relatively insoluble in water in comparison with the "C" salt, which is extremely soluble. (Compare the solubilities of curd soap containing stearate with pure sodium oleate.) The solubility is, of course, an important factor from the hypodermic injection point of view. Mr. Martindale adds that to break up the "A" salt and free it from palmitate is possible though difficult, so as to test if the therapeutic activity of chaulmoogra oil is really due to true chaulmoogric acid, palmitic acid being excluded, and he has sent out samples of each of these substances to Sir Leonard Rogers. Dr. McCoy and Dr. Hollmann express the opinion, however, that none of the derivatives offer any advantages over the oil itself, which can be administered in several ways, either by the mouth or by hypodermic injection alone, or in conjunction with other substances, such as guaiacol, camphor, or resorcin. Sometimes the oil is prepared for use by washing with alcohol, or it may be sterilised by heat, before being injected hypodermically. When given by the mouth it may cause nausea or give rise to other signs of gastric irritation. The hypodermic injections have at times caused complications such as abscess, nervous manifestations, heart failure, or sudden embarrassment of the respiration, so that the remedy requires to be administered, at first at least, with care and caution. Dr. Victor Heiser, Director of Public Health in the Philippine Islands, has used the hypodermic injections, and in a report published in October, 1914, on 9 cases treated by this method, in whom the treatment was continued long enough to give a fair trial, he stated that 5 of the patients apparently made a recovery from the clinical point of view; 3 showed marked, and 1 slight, evidence of improvement. Dr. McCoy and Dr. Hollmann used chaulmoogra oil at the Molokai leper settlement, Hawaii, in many cases, administering it sometimes in one way and sometimes in another, the majority taking it by the mouth in gelatine capsules. Few of the patients, however, took this remedy alone, for there is always a temptation to give "anything and everything that might possibly be of benefit to the patient." Out of 42 cases thus treated 16 received hypodermic injections for periods varying from 10 to 17 months, with the result that 10 were improved, 4 remained *in statu quo*, and 2 got worse. The remaining 26 patients had not continued the oil long enough to enable a proper judgment to be passed upon its effects. It may be added that in all these cases carbon dioxide snow was applied locally to the leprous sores. The personal experiences of Dr. McCoy and Dr. Hollmann lead them to conclude that chaulmoogra oil is helpful to many, perhaps to the majority, of cases of leprosy. The hypodermic method of administration, while not free from disagreeable complications at times, seems to have given good results, and therefore a further and more extended trial is warranted. They are sure, however, that the use of chaulmoogra oil as at present practised "is not the solution of the problem of the therapeutics of leprosy."

SPIROCHÆTAL STOMATITIS.

THE observations of Vincent in 1898 first drew general attention to the form of faucial inflammation with formation of false membrane which is associated with the presence of spirilla or spirochætes and of fusiform bacteria, and the name Vincent's angina is now well recognised as applied to this condition,[1] which had previously been confounded with other membranous affections of the throat. The seat of this spirochætal infection,

[1] THE LANCET, 1906, i., 1261.

however, is not confined to the tonsils and their neighbourhood, but the mouth may be the part attacked, the affection then taking the form of an ulcero-membranous stomatitis and gingivitis. In conditions of lessened resistance, due to overcrowding or other depressing circumstances, the disease may appear in epidemic form, and the importance of this infection among troops is shown in a paper by Captain Frederick B. Bowman, C.A.M.C., which is published in the Proceedings of the Medical Section of the Royal Society of Medicine for March. In the cases which form the subject of this report, embracing both officers and men, constitutional disturbance was well marked, and great depression was a characteristic feature. Ulceration occurred on the tonsils, gums, tongue, and mucous surfaces of the cheeks, and the sublingual and parotid glands were affected. The breath was peculiarly foul, and the patients complained of an offensive taste. The gums became spongy and retracted and bled easily, and the teeth in some instances became loose and tender on being tapped. The temperature varied between normal and 102° F. The infection can be conveyed by dental instruments and also probably by eating and drinking utensils. The causal organisms are readily recognisable in smears stained by methylene blue or Giemsa's stain, and can be cultivated anaerobically in peptone broth along with a little ascitic fluid and a fragment of sterile tissue (Macleod's method). An effective treatment for this condition consists in swabbing the ulcers with a mixture consisting of half an ounce of wine of ipecacuanha, one drachm of glycerine, and three drachms of Fowler's solution, and in cases in which the gums are affected this solution should be carefully applied to all pockets around the teeth. The affection must be distinguished from diphtheria, syphilis, and mercurial stomatitis, as well as from simple pyorrhœa alveolaris. In the form which affects the gums the infection is very obstinate, and owing to the depression produced is of considerable importance from a military point of view as producing prolonged incapacity for duty.

EXPERIMENTAL OSSEOUS SPOROTRICHOSIS.

WE have received from Dr. D'Agata, of the Royal Institute of Clinical Surgery at Florence, a résumé of a paper published by him on this subject. In 1912 he communicated to the Italian Surgical Society a case of primary osseous sporotrichosis of the upper jaw in which the sporotrichium Beurmanni was isolated. From this strain he instituted a series of experiments on rats and white mice, inoculating into the peritoneal cavity and subcutaneous tissue over the bones of the hind limbs a broth culture. Some of the animals died spontaneously, others were killed at different periods from a few days to three months after the injection. In the majority of the cases, from 20 to 40 days after the peritoneal injection, he found the parietal and visceral peritoneum covered with small greyish-white smooth nodules varying in size from a pin's head to a large shot. Histologically they showed three zones, corresponding to the ecthymatiform, the tuberculoid and the syphiloid of French authors. In 10 out of 15 mice thus injected there were osseous foci of sporotrichosis in various stages of evolution in the cartilages, and especially in the epiphyseal regions; there were also cases which showed osteitis of the hypertrophic variety. One of the experiments was particularly noteworthy: that of a mouse injected intraperitoneally and killed after 28 days. In this animal there were only a few lesions in the parietal peritoneum, while in the left tibia there were foci of diffuse osteomyelitis with intra-osseous abscess, and in the neighbourhood of the right tibio-tarsal joint a large serous cyst with a sporotrichositic nodule implanted in the wall on one side. Subcutaneous injections near the tibio-femoral joint almost invariably caused after 20–30 days sporotrichotic inflammatory foci in the peri-articular ligaments, giving rise to local suppuration which frequently discharged externally. In some animals subcutaneous injection produced gummatous lesions at the site of inoculation. Smears from the centre of these showed oval bodies such as have been described as representing the parasitic form assumed by the sporotrichium Beurmanni in human lesions and in those produced experimentally in animals.

DIFFERENT NAMES FOR IDENTICAL SUBSTANCES.

WE have on several occasions referred to the difficulties that may and do arise from the practice of bestowing different names upon identical substances, the position occurring more often in practical therapeutics in connexion with the synthetic products. When a single synthetic product earns more than one name a real trouble to the medical profession is introduced, and we may fairly call upon the great pharmaceutical chemists and scientific drug-houses to assist us by refusing to perpetuate this trouble, an example of which has been brought to our attention this week. The substance p-toluene-sodium-sulphochloramide was suggested as a wound antiseptic by Dr. H. D. Dakin, working in conjunction with Professor J. B. Cohen. This substance has already met with considerable success. The theoretical basis of the work, full details of the preparation of the substance, and the early practical results of its use have been already published.[1] It is said that the name "chloramine" suggested by the scientific workers responsible for its introduction, has already been appropriated, and the new name "tolamine" has been substituted by Messrs. Burroughs and Wellcome, who have registered tolamine as a trade-name for chloramine-T. We feel that it is necessary to point out that anyone ordering the substance as "tolamine" will be using the proprietary name of a particular firm and not the name preferred by the authors of the substance. The designation of the substance as chloramine-T, as suggested by its originators, should, in our opinion, be generally adopted, as the use of different names for identical substances is a serious source of trouble to medical men.

Mr. Charles Yelverton Pearson, M.D., F.R.C.S., has been appointed one of H.M. honorary surgeons in Ireland in the room of the late Sir Charles Bent Ball, M.D.

Mr. S. H. Renshaw has promised £2000 to Bury Infirmary to endow two beds—one in memory of his wife, and one in memory of his son who was killed in action at the Dardanelles.

FOOD ECONOMICS IN RELATION TO THE WAR.

BY HARRY CAMPBELL, M.D. LOND., F.R.C.P. LOND.,
PHYSICIAN TO THE WEST END HOSPITAL, LONDON.

III.[1]

The Limitation of the Quantity of Food to a Sufficiency.

FOOD not only occupies the unique position among the different forms of wealth of being the only one which is essential to life: it has the further characteristic (in common with a few other commodities, such as alcohol, tobacco, coal, and petrol) that its use involves its immediate destruction. The clothes we wear may last us months, even years, our dwellings may outlast centuries, but the food we eat is rapidly consumed within the body. It will thus be seen that any consumption of food beyond what is actually needful constitutes a net waste of the most important form of wealth, and this at the time when the strictest economy is called for. Those who delight in ethical subtleties might take as an interesting subject for discussion the question whether the thief or the glutton is the greater sinner. It would be open to anyone to argue that robbery is a less deadly sin than gluttony, seeing that the one consists in a mere transference of wealth, while the other involves a useless and even harmful destruction of it. Many people eat more than they require; not a few as much as would suffice for two, nay, even three persons. A saving of wealth running into millions could be effected if only those who exceed were to reduce their rations to the actual needs of the body. Excessive eating not only constitutes a waste of national wealth, it also injures the health. It is a trite but true saying that more people die from over-eating than from over-drinking. The transgressor in diet, moreover, is less efficient as a citizen, and at the present time we all need to be at our very best, mentally and physically. Yet I see little attempt in clubs and restaurants to economise in food. I recently estimated that the regulation supply of food at a prominent London club was about twice the quantity actually necessary, and a large proportion of the habitués gave evidence of the havoc which prolonged over-eating had wrought in their tissues. I lately heard a visitor to a country hotel remark to the landlord upon the abundance of the fare he provided. "Yes," was the proud rejoinder, "this is a house of plenty." At the fashionable West End restaurants food and drink are as lavishly consumed at the present time of crisis as in the piping times of peace. I think it possible that food is supplied too generously in some of our public institutions. At a large London workhouse which I visited some years ago it seemed to me that the supply of bread was more than was necessary, certainly in the case of some of the inmates.

I am convinced that the quantity of food required to maintain in health a person not engaged in strenuous muscular exercise is much less than is generally supposed. Young adults need more food than older people—our food requirements diminish with advancing years—yet it is surprising how small an amount of food even young people leading active lives can thrive on. Thus the diet of a young woman weighing 10½ st., the embodiment of healthy womanhood, whose daily routine is one long round of activity—bustling about the house, riding, driving, walking, &c., is somewhat as follows: Breakfast: A little bacon or fish, or an egg, with a couple of slices of bread-and-butter. Midday dinner: Equivalent to what a town-dweller would regard as a moderate lunch. Tea: A little bread-and-butter. Before going to bed: An apple or some other fruit. On this diet she keeps her weight, looks a picture of radiant health, never feels tired or unpleasantly hungry, and can always forego a meal without discomfort. The following is the diet of a London postman, aged 26, who walks about 15 miles in the day, and on some beats has to mount some 5000 steps daily (he carries a weight not exceeding 30 lb.): 5 A.M., a piece of toast and a cup of tea; 9 A.M., one rasher of bacon, four moderate slices of bread-and-butter, two cups of tea; 2 P.M., chop or cut off the joint, four potatoes, and green vegetables; 6 P.M., a bloater (or some other fish), four slices of bread-and-butter, one cup of tea. I could furnish many similar instances. Cases of this kind—and they are quite common—show how little food is needed in perfect health, even in the heyday of youth, and when a considerable amount of muscular work is being performed. They probably indicate the possession of a well-nigh ideal digestion. Others apparently healthy no doubt require a somewhat more generous diet.

The two chief factors which make for excessive eating are the appetising nature of the food and the softness of the vegetable (especially the farinaceous) portion of it. The object of the cook is to make her dishes as tasty as possible, and so to arrange their order that the appetite shall not flag throughout the meal. As to the second factor, it is obvious that soft farinaceous foods, such as porridge and milk puddings, which rapidly find their way into the stomach, are more likely to be taken in excess than firmer food, such as crusty bread, which calls for thorough mastication. The more completely farinaceous food is masticated the smaller is the quantity that will be needed to satisfy the appetite.

Another cause of excessive eating depends upon the principle that "appetite increases by what it feeds on." The more one accustomes oneself to eat largely the more clamant does the appetite become. Excessive eating, indeed, tends to beget an actual craving for food not unlike the morbid craving for stimulants. When the meal-time comes round, or even before, there is felt a sinking or other uncomfortable sensation at the pit of the stomach, or perhaps a feeling of lassitude. These feelings being relieved by food, it is erroneously concluded that they indicate the need for a restoking of the vital engine. That this view is entirely wrong is shown by the fact that many a healthy person, expending a good deal of muscular energy and consuming but a moderate quantity of food, can forego a meal without inconvenience. Even more significant is the fact that the habitual over-eater generally feels brighter and more vigorous after enforced abstinence, such as may be necessitated, e.g., by a bilious headache or an attack of gout. The machine is found to work better when the stoking ceases. The fact is, the unpleasant feelings referred to are not due to the lack of nutriment and do not indicate the need for more. The "sinking" results from the absence of the wanted mechanical stimulus afforded by a bulky meal; the lassitude is due to a poisoned state of the blood brought about by

[1] Nos. I. and II. were published in THE LANCET of March 25th (p. 685) and April 1st (p. 742) respectively.

chronic over-eating, and is removed temporarily by the absorption of the more diffusible, stimulating elements of the food. In this way the effects of the blood poisoning are for the time masked.

The over-eater, like the alcoholic inebriate, rarely realises that he is indulging in an injurious excess. In deciding whether too much food is being taken or not, the body weight affords useful help. If a person's weight is not above the normal the probability is that he is not eating too much, but if he is decidedly stout he very probably is over-eating. This test is not, indeed, infallible; we occasionally meet with thin people who eat abundantly and stout people who are moderate eaters. What is so frequently forgotten is the fact that the amount of food taken should be proportioned to the amount of muscular energy expended. If a person takes little exercise he requires proportionately less food, just as it requires less petrol to drive a car five miles than fifty. When a person who takes little exercise gets fat his fatness should not be put down to the lack of exercise, but rather to the fact that his supply of food is in excess of the amount of muscular energy expended. The London policeman probably consumes as much as the London postman, although he does not expend more than a quarter of the muscular energy expended by the latter. It is clear, therefore, that he eats more than is necessary—a conclusion which is not infrequently borne out by the amplitude of his proportions. It is as rare to meet a thin policeman past 30 in our towns as it is to see a stout postman anywhere. Stout people often resent the charge that they eat too much, and insist that they are very moderate eaters. Investigation generally shows otherwise, but whether they eat much or little the fact remains that in the vast majority of cases they eat more than they require.

All those who on reflection have reason to suspect that they may be eating superabundantly should, alike in their own and nation's interest, cautiously begin at once to cut down their rations. In this way they can improve their health, render themselves more efficient citizens, and save the wealth of their country. It is not suggested that a large reduction should be made suddenly. Rather should an attempt be made to accustom the body gradually to do with less and less food. To this end the food should be plain, not too appetising, and well masticated. Unfortunately, the British people are the most inefficient masticators in the world. I will now endeavour to explain how this bad habit has arisen, and to indicate some of the evils which result from it.

Mastication.—Efficient mastication among other advantages makes for economy in food, inasmuch as it promotes normal digestion and in this way reduces the amount of food needful to sustain the body. It is not generally known that it is essentially the vegetable portion of our food which demands mastication. The carnivora do not masticate their food, as anyone who has observed a dog bolt a piece of meat can testify; their teeth interlock and do not admit of any lateral grinding action. On the other hand, all the vegetable-feeding mammals are laborious masticators. This is because vegetable food consists of a cellulose framework more or less dense, which it is necessary to break up, so as to liberate the contained nutrient particles and allow them to come under the action of the digestive juices. That our ape-ancesters subjected their food to prolonged mastication is evident from a study of the teeth of their near relatives, the larger manlike apes (gorilla, chimpanzee, and ourang). I find that even the milk teeth of these animals are greatly worn down. Before man learnt to prepare his vegetable food artificially by maceration, grinding, and cooking, he had to subject most of it to a prolonged natural milling with his teeth. Our teeth have been to a great extent relieved of this laborious work by the miller and the cook. The saving of the work of mastication thus effected has certain manifest advantages, but these are largely discounted if the farinaceous food is rendered so soft that it is swallowed without being subjected to any but the merest pretence at mastication, for then not only is it not properly mixed with the saliva, but the teeth and salivary glands are cheated of their normal work. Now, unfortunately, in this country we consume all, or nearly all, our vegetable food in soft, pappy, pultaceous and spongy forms, with the result that we have come to be a nation of veritable food-suckers, with atrocious teeth, misshapen jaws, and none too good digestions. Our sole vegetable foods which invite mastication are crusty bread, dry toast, hard biscuits, salads, nuts, and apples. Our staple vegetable food, bread, is eaten in a spongy form. The loaves are shaped so as to give a minimum of surface for crust, and are lightly baked so that the crust shall be as thin as possible. In the "A. B. C." shops it is the custom when cutting the rectangular loaves into slices to put aside the end pieces, as the customers refuse to eat them. I am told by a Scotch baker that the most crusty loaves—those which rest on the floor and against the sides of the oven—fetch a lower price than the others, so rooted is the objection of the Scotch people to crusty bread.

Let us now consider the foods which form the bulk of our national vegetable diet. They are: soft spongy bread, bread-and-milk, cooked vegetables, puddings (suet, batter, "Yorkshire," plum, cabinet, milk, &c.), porridge, cakes (multitudinous), buns, scones, muffins, crumpets, tea-cakes, and fancy cakes galore. To set forth in detail the many evils which result from this pernicious system of diet would require several articles. The one I desire to emphasise just now is that it causes an excess of farinaceous food to be consumed. The more thoroughly a farinaceous food, such as bread, is chewed, the more intimately will it be mixed with the saliva, and the more efficiently is it likely to be digested; and it goes without saying that when food is well digested less of it will be required than when it is not. A piece of crusty bread, thoroughly masticated, will go a longer way to satisfy the appetite and the nutritive requirements of the system than an equivalent of pudding hastily swallowed.

The best way to secure adequate mastication is to choose foods which invite, or even compel, mastication. It is chiefly in regard to the cereal foods—wheaten flour, oatmeal, and rice—that reform is most needed. From the point of view of mastication oatmeal biscuits are preferable to oatmeal porridge, but the latter is so popular and valuable a food that it may be permitted with the proviso that it be subjected to some sort of chewing, and not allowed to flop like some huge poultice into the stomach. Wheaten flour—our staple vegetable food—should be employed for little else than bread, suet pudding (plain suet pudding, fruit pudding, meat pudding), plain biscuits, and home-made cake. Other puddings and the multitudinous varieties of cakes known to the pastry-cooks should be banned;

they have no special virtue and they can well be dispensed with. When a patient is knocked off his puddings or "sweets" by his doctor he often asks in a concerned or even injured tone what he can eat instead? The answer is that bread-and-butter (i.e., flour and fat) is as nutritious as any ordinary pudding and more wholesome than most. It is a good food because it is nutritive, simple, and (if the bread is crusty) compels mastication. It is, of course, chiefly in the form of bread that wheaten flour should be consumed. The loaves should be shaped so as to give a maximum surface for crust (spindle-shaped, or cylindrical-shaped) and well baked, so as to give a thick but not too hard or brittle crust. Unfortunately, many people are prevented by bad teeth from eating crusts.

Defective teeth.—Here I am led to say a few words about the deplorable condition of the teeth of our countrymen, the more so as the fact has recently been brought into prominent notice in connexion with our recruits. This state of things is a national disgrace. It is solely due to our faulty dietetic customs—above all to the practice of eating sweets and soft farinaceous food, which leaves the mouth in a chronic unhygienic condition. I estimate that there are among the inhabitants of these islands upwards of 200 millions of carious teeth, and probably an even greater number of socket abscesses (pyorrhœa alveolaris), while as to the jaws, it is rare to meet a normal one. One of the first things which strike the observant foreigner when he lands upon our shores is the large number of people with false teeth, and the great length and prominence of the natural teeth—a feature which the continental cartoonist has not been slow to accentuate. These obtrusively large teeth constitute a damning indictment against our habit of consuming nearly all our vegetable food in a form which does not put the teeth to adequate use. Teeth which are not put to vigorous use are not ground down as they should be, and they tend also to "grow out of their sockets," so that they, or rather the visible parts of them, become longer. This lengthening of the teeth is due in an even greater degree to pyorrhœa. Hence pap-fed people tend to be "long in the tooth."

We are happily beginning to awake to the necessity of looking after our children's teeth, and dental surgeons have been appointed to tend the teeth of the elementary-school children. This is a move in the right direction, but it is little more than shutting the stable-door after the horse has bolted. Dentists are mainly engaged in an endeavour to repair damaged teeth. Obviously our aim should be to prevent the damage, and this, as Dr. Sim Wallace has shown, can be done by choosing foods which exercise the teeth and salivary glands adequately, and by so arranging the order of them in a meal that the mouth shall be left in a sanitary condition.

So accustomed are we to the prevalence of dental disease in this country that we accept it as a matter of course. It is, however, a serious national evil, but happily one which can be remedied. The present time, when for reason of economy we are called upon to examine into and revise our dietetic habits, is a good one to put up a bold fight against it.

Wimpole-street, W.

A DEVONSHIRE CENTENARIAN.—Miss Emily Bond, daughter of the late Admiral Bond, who celebrated the hundredth anniversary of her birthday last June, died at Exeter last week.

THE CULTURE OF MEDICINAL HERBS.

THE letter of a correspondent in our last issue (p. 749) suggests the importance of growing wintergreen and willow within the British empire to assure a supply of salicin. The culture of medicinal herbs in general is a question well worthy of consideration at the present moment.

There was a time when no village garden was complete without its bed of simples from which the medicine-chest was regularly replenished, and although with the coming of the age of machinery the practice largely lapsed in this country, it still persists unchanged in the country of our nearest neighbour and ally, now much more largely agricultural than these islands. Here during the summer and autumn months family groups may constantly be seen sitting in their courts and doorways preparing the leaves and flowers which are to form the basis of the "*tisanes*," the famous domestic remedies for all minor ills. There are, of course, a number of herb-farms in Great Britain where cultivation of certain herbs is carried out and where others have been definitely abandoned as unprofitable—e.g., in the case of dandelion root, in which the cost of cultivation is greatly more than that of digging the weed. The practice may have a kind of popular revival in this country in view of the shortage of vegetable drugs of all kinds caused by the closing of the frontiers of the Central European States with their vast tracts of land and multitudes of rural population willing to collect leaves and roots. The revival is being promoted by the Herb-Growing Association[1] which is affiliated to the Women's Farm and Garden Union, who have undertaken to give advice to their members on herb-growing and the preparation and disposal of herbs, so that the market may not be overstocked with some and be short of others. It is pointed out that since the dealers buy in hundredweights, the small grower who has only a few pounds for the market would have difficulty in disposing of her crops except for some such coöperative system as is provided by the Association.

The difficulties to be faced are not small and must be carefully studied if there is to be any prospect of success. Many herbs are very slow growing, and it is long before the medicinal property is developed. The lack of belladonna extract is largely due to the fact that the culture of the Atropa belladonna requires much ground, and that the roots are not available to lift and dry on a profitable scale until the third year. Then not every soil or situation is suitable to develop the production of the useful drug in the herb. It is well known that the opium poppy, even if it grows freely in this climate, does not yield any considerable proportion of the morphine alkaloids. It is not accidental enterprise which has located the fields of peppermint and lavender at Mitcham and Hitchin; there are certain properties in the soil and local climate which bring about a maximum yield of the essential oil in the growing Mentha piperita and Lavandula vera. Experience, too, has shown that the growing of drugs cannot successfully be undertaken for any period of years except as part of a general farm. Land very soon gets "sick" of these herbs, and the crop no longer pays for the growing. Particularly is this so with belladonna and henbane.

Collection of wild herbs, on the other hand, is simpler and offers a useful field. The collector turns his attention from one to another herb, according to the season and the larger or smaller demand. No large outlay of capital is necessary, nor any waiting for a return on the labour and money expended. But the collection of wild-flower products too has its special difficulties. The autumn crocus, more correctly colchicum, is widely scattered over the flat river-meadows in many parts of this country, and the bulbs are betrayed by the large lily-like leaves which appear in the early spring. But the bulbs lie deep, and unless closely set, as they often are in a Swiss meadow, they will require an immensity of labour and a great destruction of the surface of a meadow before any considerable quantity has been grubbed up, although we have heard of an active man who was able to earn 27*s.* a week by so doing. In the second place, the question of drying is a crucial one. In most countries where leaves and flowers are gathered they can be

[1] The secretaries of the Herbal Subcommittee of the Women's Farm and Garden Union are Miss E. L. Chamberlain, F.R.H.S., and Miss Alice Sandford, to whom communications should be addressed at 45, Queen Anne's Chambers, S.W.

left to dry in the sun or under cover in the open air and retain all their essential ingredients unimpaired. Visitors to any sub-alpine or alpine meadow in the spring or summer will have noticed how each leaf and flower retains most of its form and colour in the process of drying to hay. Up and down this country we have abundance of foxglove leaves to prepare all the tincture and infusion that we use, but unless special facilities are provided for drying them or unusual meteorological conditions prevail the leaves will become mouldy or their contained glucosides be washed out or ferment before they reach the factory where the extraction is to take place.

The Women's Herb-Growing Association has therefore embarked on an enterprise which will require both expert knowledge and much careful organisation to make it a success. And we should say that success is much more likely to attend the collection of wild herbs than their cultivation. If cultivation is undertaken we have seen that two years or more may elapse before a crop can be obtained. Then if the supply exceeds the demand this crop when obtained will be unsaleable, as the manufacturers will naturally only buy sufficient to last from season to season, avoiding an accumulation of old and deteriorated herbs. Again, the absence of supplies from Central Europe has not only greatly raised prices but has also stimulated the organised collection of wild herbs in other parts of Europe—for example, in Switzerland, Spain, and Northern Italy, whence the supply may very soon again exceed the demand. India is offering considerable quantities of drugs, such as belladonna, of which the alkaloidal content has been found satisfactory. In normal times Belgium is our chief source of valerian and camomile, and doubtless will become so again.

In Australia the question is being seriously considered by the Commonwealth authorities, and it is stated in *Science Progress* that a board has been appointed to inquire into the whole matter, and, if possible, to establish the cultivation of medicinal plants on practical commercial lines. At first it is proposed to import seeds and plants and allocate them to the high schools to be tested in the school gardens. The produce will be tested at the laboratory of the Department of Agriculture, by which means it is hoped to obtain the necessary data to allocate the various plants to the districts best suited to them. Similar help might well be provided in this country to the industry of growing medicinal herbs.

THE SERVICES.

ARMY MEDICAL SERVICE.

Lieutenant-Colonel G. St. C. Thom, R.A.M.C., to be a Deputy Assistant Director-General, vice Lieutenant-Colonel W. R. Blackwell.

ROYAL ARMY MEDICAL CORPS.

The undermentioned are granted temporary rank whilst employed at the County of Middlesex War Hospital:—Temporary Major L. W. Rolleston, from the Napsbury War Hospital, to be Lieutenant-Colonel. Temporary Captain A. O'Neill, from the Napsbury War Hospital, and L. S. T. Burrell to be Majors. H. F. B. Roberts and H. C. Halsted to be Captains.

W. D. Anderson to be temporary Major.

The undermentioned to be temporary Honorary Majors:—W. I. de C. Wheeler and Temporary Honorary Lieutenant L. J. Austin, whilst employed with No. 2 British Red Cross Hospital, and Temporary Honorary Captain S. W. Patterson, whilst serving with the Australian Voluntary Hospital.

Temporary Captain A. S. Fry relinquishes his commission on appointment to the Indian Medical Service. Temporary Captain C. H. Mills relinquishes his commission.

The undermentioned to be temporary Captains:—A. S. Garden, G. J. Arnold, late Captain, R.A.M.C. (T.F.), and Staff-Surgeon G. H. Ross, Retired List, R.N.

The undermentioned temporary Lieutenants to be temporary Captains: G. M. De Vine, D. E. Derry, E. L. Mansel, T. E. Hammond, J. Marmion, C. W. Donald, F. G. Milne, T. F. Griffin, D. Bird, G. N. Lorimer, W. J. Lascelles, A. G. MacLeod, E. A. O. Travers, P. Carney, W. Thomas, J. H. Askins, H. H. Elliot, J. Sullivan, H. L. C. Noel, G. S. Phillips, M. E. Robinson, H. N. M. Puckle, R. M. Clarke, A. T. Roberts, G. D. K. Waldron, J. I. M. Jamieson, W. E. Giblin, W. A. Edwards, L. J. J. Nye, F. E. Keane, O. H. Edwards, F. Irvine, W. Smithies, H. H. Davis, C. E. Sundell, J. R. Slack, T. Sheehan, A. Wiley, F. S. Hawks, J. A. Hutchinson, F. H. Rudge, N. G. Horner, D. C. Taylor, W. W. Turner, W. M. O'Connor, H. B. Binks, A. H. Davidson, A. C. Freeth, M. L. Neylon, N. W. Steinberg, J. Hutchison, G. Riddoch, V. J. McAllister, W. W. Thomson, A. T. Paterson, A. C. A. Jekyll, C. K. Cohen, E. P. Dark, R. V. Steele, S. E. Elphick, E. J. Eedle, R. B. Hunt, C. Stuart, M. A. Farr, H. Mathewson, J. W. Wood, J. S. Caldwell, W. Morrison, R. H. Scovell, and O. H. Bowen.

E. C. Austin to be temporary Honorary Captain whilst employed at the Withington War Hospital, Manchester.

Temporary Captain S. P. Bedson, from a Service Battalion, The Northumberland Fusiliers, to be temporary Lieutenant.

The undermentioned to be temporary Lieutenants: E. C. Lindsey, J. Hewat, F. L. Gill, H. S. Gaskell, D. Morrison, P. J. Maguire, T. R. Hunter, E. J. Dermott, D. C. Suttie, G. F. Forde, W. J. McIvor, R. J. P. Waugh, W. Halliwell, B. P. Allison, T. W. Mason, G. J. Knaggs, R. W. Chapman, A. Walker, W. J. Evans, J. A. H. Telfer, F. J. H. Begg, Temporary Honorary Lieutenant J. N. Deacon, T. Perrin, F. L. Keith, H. A. Macdonald, T. P. Hutchison, J. L. Power, H. Tipping, W. A. Shafto, A. Pimm, J. E. Harford, W. W. W. Watt, and P. Figdor.

The undermentioned Cadets, Edinburgh University Contingent, Officers Training Corps, to be Lieutenants (on probation):—Lance-Corporal W. H. Ferguson, Lance-Corporal H. D. Wright, and K. P. Brown.

Canadian Army Medical Corps: Major C. P. Templeton to be temporary Lieutenant-Colonel. Lieutenants to be temporary Lieutenants: D. E. H. Cleveland, J. B. Galligan, T. A. MacKenzie, F. H. Hurlburt, M. D. Baker, E. C. Smith, D. T. Evans, J. G. Lee, and G. A. Lamont. The undermentioned temporary Lieutenants relinquish their commissions on account of ill-health: C. G. Sherowitz and F. W. Lee.

SUPPLEMENTARY TO REGULAR UNITS OR CORPS.

Captain G. V. Stockdale to be temporary Major whilst commanding a Field Ambulance from Jan. 4th to Feb. 7th. Captain C. Lovell to be temporary Major whilst commanding a Field Ambulance.

TERRITORIAL FORCE.

Royal Army Medical Corps.

Scottish Horse Mounted Brigade Field Ambulance: Major H. Richardson to be temporary Lieutenant-Colonel whilst in command of a Field Ambulance.

Yorks Mounted Brigade Field Ambulance: Lieutenant C. G. Meade to be Captain.

West Lancs Field Ambulance: Captain (temporary Major) A. P. H. Simpson relinquishes his temporary rank on alteration in posting.

Lowland Field Ambulance: Captain W. W. Greer to be temporary Major whilst in command of a Field Ambulance. Lieutenant W. Combe to be Captain.

Northumbrian Field Ambulance: Lieutenants John A. L. Magee and J. B. Sinson to be Captains.

West Lancs Casualty Clearing Station: Captain A. P. H. Simpson, from West Lancs Field Ambulance, to be Captain.

Welsh Border Mounted Brigade Field Ambulance: H. A. Higginson to be Lieutenant.

London Field Ambulance: Major W. G. Macfee, from Attached to Units other than Medical Units, to be Major.

Home Counties Casualty Clearing Station: Captain R. W. Brimacombe to be temporary Major whilst in command of a Casualty Clearing Station. Temporary Honorary Lieutenant W. Burt, from the Red Cross Hospital, Netley, to be Lieutenant.

Highland Casualty Clearing Station: F. G. Stuart to be Lieutenant.

South Midland Mounted Brigade Field Ambulance: Lieutenant W. G. Rutherford to be Captain.

East Anglia Field Ambulance: Lieutenant S. D. Graham to be Captain. Lieutenant R. J. R. Mecredy, from East Anglia Field Ambulance, to be Lieutenant.

North Midland Field Ambulance: Lieutenant T. E. A. Carr and Lieutenant (temporary Captain) G. Holmes to be Captains.

Attached to Units other than Medical Units.—Captain W. R. E. Williams to be Major. Captain H. F. Everett to be temporary Major whilst in command of a Field Ambulance. Captain J. J. Marsh relinquishes his commission on account of ill-health. Lieutenants E. H. Gonin and J. D. Jones to be Captains. G. H. Gill to be Lieutenant.

JOURNAL OF THE ROYAL ARMY MEDICAL CORPS.

The opening paper in the March issue of the *Journal of the Royal Army Medical Corps* is a record of observations which have been carried out at St. Bartholomew's Hospital for the Medical Research Committee by R. L. Mackenzie Wallis, demonstrator of chemical pathology, on acute nephritis, the so-called "trench nephritis." The cases referred to in the paper were mainly under the care of Captain W. Langdon Brown, who published a preliminary note on 58 cases in the July issue of the journal. A Report on Cases of Albuminuria amongst British Troops in France, by Major B. W. Hogarth; the Bacteria of Gangrenous Wounds, by Major H. R. Dean and Captain T. B. Mouat; Plates for Masking Facial Wounds, by Captain Richard Cruise, Captain Somerville Hastings, and Sergeant Derwent Wood (A.R.A.); and Field Sanitation, by Captain E. Brooke Pike, are the titles of other interesting communications. Dr. A. T. MacConkey, of the

Lister Institute, Elstree, Herts, puts forward a plea for a collective study of tetanus in which he says: "If all those who have wounded soldiers under their care will combine to study the disease and each give their help towards deciding upon the value of (1) the various premonitory symptoms; (2) the intraspinal method of administration; and (3) large doses of antitoxin, it is quite possible that we may make good progress in the direction of solving the problem of the successful treatment of tetanus."

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

In the 96 English and Welsh towns with populations exceeding 50,000 persons at the last Census, 8333 births and 5877 deaths were registered during the week ended Saturday, April 1st. The annual rate of mortality in these towns, which had been 17·2, 17·9, and 16·4 per 1000 in the three preceding weeks, rose in the week under notice to 16·9 per 1000 of their aggregate population, estimated at 18,136,180 persons at the middle of the year 1914. During the 13 weeks of the quarter just ended the mean annual death-rate in these towns averaged 15·7, against a corresponding rate of 15·3 per 1000 in London. The death-rate last week ranged from 7·5 in Southend-on-Sea, 8·0 in Ilford, 8·1 in Edmonton, 9·4 in Enfield, and 9·7 in Barnsley, to 23·4 in Aberdare, 24·0 in Southport, 25·1 in Liverpool and in West Hartlepool, 27·6 in Sunderland, and 29·3 in Rochdale.

The 5877 deaths were 155 in excess of the number in the previous week, and included 420 which were referred to the principal epidemic diseases, against numbers increasing from 345 to 391 in the three preceding weeks. Of these 420 deaths, 134 resulted from whooping-cough, 122 from measles, 71 from diphtheria, 66 from infantile diarrhœal diseases, 20 from scarlet fever, and 7 from enteric fever, but not one from small-pox. The death-rate from these diseases was equal to 1·2, against 1·1 per 1000 in each of the two preceding weeks. The deaths attributed to whooping-cough, which had been 85, 93, and 137 in the three preceding weeks, fell to 134, and included 37 in London, 15 in Manchester, 9 in Liverpool, 8 in Birmingham, 6 each in Derby and Sheffield, and 5 each in West Ham and Leyton. The deaths referred to measles, which had been 121, 127, and 115 in the three preceding weeks, rose to 122, and caused the highest annual death-rates of 1·8 in Leicester, 2·6 in Swansea, 2·7 in Great Yarmouth, 3·3 in Stockport, and 5·5 in Rochdale. The fatal cases of diphtheria, which had been 54, 61, and 53 in the three preceding weeks, rose to 71, of which 17 were registered in London, 6 in Birmingham, 4 each in West Ham and Liverpool, and 3 each in Stoke-on-Trent and Wolverhampton. The deaths of infants (under 2 years) from diarrhœa and enteritis, which had been 60, 68, and 65, in the three preceding weeks, numbered 66 and included 14 in London, 10 in Birmingham, 5 each in Liverpool and Sunderland, and 4 in Manchester. The deaths referred to scarlet fever, which had been 13, 19, and 12 in the three preceding weeks, rose to 20, of which 7 were recorded in London and 2 in Preston. The 7 fatal cases of enteric fever were 2 below the average in the earlier weeks of the quarter, and included 2 in Manchester.

The number of scarlet fever patients under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, which had steadily declined from 2257 to 1783 in the ten preceding weeks, further fell to 1768 on Saturday last; 214 new cases were admitted during the week, against 216, 193, and 210 in the three preceding weeks. These hospitals also contained on Saturday last 1427 cases of diphtheria, 242 of whooping-cough, 132 of measles, and 47 of enteric fever, but not one of small-pox. The 1465 deaths from all causes in London were 31 in excess of the number in the previous week, and corresponded to an annual death-rate of 16·9 per 1000. The deaths referred to diseases of the respiratory system, which had been 344, 405, and 337 in the three preceding weeks, further fell to 328, and were 147 below the number registered in the corresponding week of last year.

Of the 5877 deaths from all causes in the 96 towns, 191 resulted from violence and 444 were the subject of coroners' inquests, while 1783 occurred in public institutions. The causes of 59, or 1·0 per cent., of the total deaths were not certified either by a registered medical practitioner or by a coroner after inquest. All the causes of death were duly certified in Leeds, Bristol, West Ham, Bradford, Hull, Newcastle-on-Tyne, and in 67 other smaller towns. Of the 59 uncertified causes, 18 were registered in Liverpool, 6 each in Birmingham and Manchester, 4 in Preston, and 3 in West Bromwich.

HEALTH OF SCOTCH TOWNS.

In the 16 largest Scotch towns with an aggregate population estimated at 2,364,500 persons at the middle of this year, 1148 births and 903 deaths were registered during the week ended Saturday, March 25th. The annual rate of mortality in these towns, which had increased from 15·5 to 20·7 per 1000 in the five preceding weeks, fell to 19·9 per 1000 in the week under notice. During the first 12 weeks of the quarter just ended the mean annual death-rate in these towns averaged 16·4 or 0·8 per 1000 above that recorded in the large English towns. The death-rate during the week ranged from 13·3 in Leith, 14·5 in Aberdeen and 15·8 in Perth, to 23·8 in Paisley, 26·8 in Greenock, and 28·0 in Kilmarnock.

The 903 deaths from all causes were 35 fewer than the number in the previous week, and included 82 which were referred to the principal epidemic diseases, against numbers rising from 56 to 89 in the three preceding weeks. Of these 82 deaths, 43 resulted from measles, 15 from diphtheria, 12 from infantile diarrhœal diseases, 8 from scarlet fever, 3 from whooping-cough, and 1 from enteric fever, but not one from small-pox. The annual death-rate from these diseases was equal to 1·8, or 0·7 per 1000 higher than that recorded in the large English towns. The deaths attributed to measles, which had been 23, 31, and 42 in the three preceding weeks, were 43, and included 21 in Glasgow and 5 each in Greenock, Coatbridge, and Kilmarnock. The deaths referred to diphtheria, which had been 10, 7, and 16 in the three preceding weeks, numbered 15, of which 5 were registered in Edinburgh, 4 in Glasgow, and 2 in Paisley. The fatal cases of diarrhœa and enteritis (among infants under 2 years), which had been 8, 8, and 11 in the three preceding weeks, were 12 in the week under notice, and included 4 in Glasgow, 3 in Dundee, and 2 in Clydebank. The deaths attributed to scarlet fever, which had been 9, 6, and 12 in the three preceding weeks, fell to 8, and comprised 6 in Glasgow and 2 in Paisley. The deaths from whooping-cough were slightly below the average in the earlier weeks of the quarter, and were recorded in Glasgow, Leith, and Kirkcaldy. The fatal case of enteric fever occurred in Glasgow.

The deaths referred to diseases of the respiratory system, which had increased from 88 to 195 in the five preceding weeks, further rose to 212 in the week under notice, and were 26 above the number registered in the corresponding week of last year. The deaths from violence numbered 29, against 29 and 26 in the two preceding weeks.

HEALTH OF IRISH TOWNS.

In the 19 town districts of Ireland with populations exceeding 10,000 persons at the last Census, 561 births and 535 deaths were registered during the week ended Saturday, March 25th. The annual rate of mortality in these towns, which had been 21·5, 24·5, and 21·3 per 1000 in the three preceding weeks, rose in the week under notice to 24·3 per 1000 of their aggregate population, estimated at 1,148,468 persons at the middle of last year. During the first 12 weeks of the quarter just ended the mean annual death-rate in these towns averaged 20·1, against corresponding rates of 15·6 and 16·4 per 1000 in the English and Scotch towns respectively. The death-rate during the week was equal to 28·2 in Dublin (against 16·6 in London and 21·1 in Glasgow), 21·3 in Belfast, 28·6 in Cork, 19·0 in Londonderry, 16·2 in Limerick, and 26·6 in Waterford, while in the 13 smaller towns the mean rate was 22·5 per 1000.

The 535 deaths from all causes were 65 in excess of the number in the previous week, and included 45 which were referred to the principal epidemic diseases, against 51 and 38 in the two preceding weeks. Of these 45 deaths, 18 resulted from measles, 15 from whooping-cough, 5 each from infantile diarrhœal diseases and enteric fever, and 2 from diphtheria, but not one from small-pox or scarlet fever. The annual death-rate from these diseases was equal to 2·0, against corresponding rates of 1·1 and 1·8 per 1000 in the English and Scotch towns respectively. The deaths attributed to measles, which had been 12, 18, and 16 in the three preceding weeks, rose to 18, and comprised 15 in Belfast, 2 in Dublin, and 1 in Cork. The deaths referred to whooping-cough, which had been 11, 10, and 8 in the three preceding weeks, rose to 15, and included 8 in Dublin and 4 in Belfast. The fatal cases of diarrhœa and enteritis (among infants under 2 years), which had been 12, 13, and 10 in the three preceding weeks, fell to 5, of which 3 were registered in Belfast and 2 in Dublin. The 5 deaths attributed to enteric fever, comprising 4 in Dublin and 1 in Portadown, were 4 in excess of the average in the earlier weeks of the quarter. The deaths from diphtheria were recorded in Belfast and Cork.

The deaths referred to diseases of the respiratory system, which had been 95, 124, and 117 in the three preceding weeks, rose to 134 in the week under notice, but were 9 below the number registered in the corresponding week of last year. Of the 535 deaths from all causes, 172, or 32 per cent., occurred in public institutions, and 6 resulted from violence. The causes of 24, or 4·5 per cent., of the total deaths were not certified either by a registered medical practitioner or by a coroner after inquest, and included 10 in Dublin, 6 in Belfast, 4 in Cork, and 3 in Wexford; in the large English towns the proportion of uncertified causes did not exceed 0·7 per cent.

Correspondence.

"Audi alteram partem."

THE DURATION OF LIFE AFTER INGUINAL COLOTOMY.

To the Editor of THE LANCET.

SIR,—An old and valued friend of mine, a well-known local solicitor, with a long record of public service, died on Feb. 18th after a comparatively short illness, at the advanced age of 84 years. I saw him in consultation with the late Dr. Samuel Fenwick and his usual medical adviser on May 23rd, 1899. He then had intestinal obstruction with severe abdominal pain, and a well-defined mass was detected in the left iliac region, but nothing was discovered in the rectum within reach of the finger. He was advised to submit to operation without delay. Two days later (May 25th, 1899) Sir Frederick Treves performed inguinal colotomy. The growth, which was circumscribed, irregular in outline, and seemed to involve the whole circumference of the gut, was situated at the highest part of the rectum close to the sigmoid flexure. The opening into the descending colon was therefore made at a higher level than usual in such cases. He made a good and rapid recovery, soon returned to his duties, and continued to work up to a few days of his death. Not many weeks ago he went to London to transact business. On more than one occasion he told me he had acquired wonderful control over his artificial anus. Under ordinary conditions he usually knew when to expect an action of the bowels, and he was seldom disturbed again the same day. The best testimony I can produce of the success of the operation is contained in a letter which has just reached me from his widow, to whom I wrote asking permission to publish this note. She writes: "Since then, he has not suffered pain—nothing more than discomfort and inconvenience, borne so patiently, and, as you know, his vigour and activity returned to him surprisingly. Probably his great energy prolonged his life and prevented him sinking into the condition of a confirmed invalid." Such a record is, I believe, unique, and must be taken into consideration in any prognosis of the duration of life after inguinal colotomy. Let me add, in conclusion, that no doubt existed in the mind of anyone present at the operation of the significance of the growth. I am, Sir, yours faithfully,

FREDERICK S. PALMER, M.D., F.R.C.P.

Wimpole-street, W., April 3rd, 1916.

THE SIGNIFICANCE OF CERVICAL CAPILLARY MARKINGS.

To the Editor of THE LANCET.

SIR,—Dr. R. Crawshaw Holt having directed my attention to the possible connexion of certain cutaneous telangiectases with pulmonary tuberculosis, I was interested when examining healthy young adult women and girls of 15 years of age to see if these markings were present. In the large majority of cases they were absent, and where I found them, with very few exceptions, I found also either signs of arrested tuberculous disease or a history more or less definite of bronchitis or pneumonia in early life. This merely points to the advisability, where such markings are present, of pursuing investigations further to see if other signs of tuberculous trouble, active or latent, may be present.

I am, Sir, yours faithfully,

Manchester, March 28th, 1916. CATHERINE CHISHOLM.

To the Editor of THE LANCET.

SIR,—In THE LANCET of March 4th Dr. R. Crawshaw Holt recorded under this heading his belief in the diagnostic importance of these venules, when occurring about the cervico-dorsal region of the spine, in suspected tuberculosis inside the chest when other evidence is equivocal. This provoked a statement from Dr. F. Parkes Weber that many healthy young subjects showed these appearances here and elsewhere, and Dr. Clive Riviere followed with an interesting account of some of his own observations made upon school children.

From a prolonged study of venous appearances on the skin of children of all ages, of which I have detailed records of about 250, I am inclined to discredit the view that this particular type of phenomenon has any connexion with pressure on the deep systems of veins, or with local vaso-motor disturbances due to visceral disease. The finer capillary markings found in this situation are exactly similar in size and aspect with those often to be seen on other parts. My observations tend rather to suggest that local mechanical conditions help to determine their appearance—e.g., the pressure and friction of clothing over prominent or relatively unyielding parts, or the long-continued chafing of two skin-surfaces together. Constitutional peculiarities of the skin also probably play a part. The sites of election are over the sternum, the region of the clavicles, the spinous processes of the vertebræ, and the inguinal regions, though they may, of course, occur elsewhere. They are also very persistent. Thus, in one of my cases, at the age of 5 years, a considerable number were present about the skin of the thorax, including the spinal region in question. Six years later there were still many to be found, those over the vertebræ being still visible. This child is robust, and has never shown any symptom or physical sign of tracheo-bronchial adenopathy or phthisis.

There are several other, and I think cogent, reasons for disputing the view put forward by Dr. Crawshaw Holt, but to enter into these would unduly prolong this letter.

I am, Sir, yours faithfully,

Liverpool, April 3rd, 1916. EDMUND HUGHES.

CERTIFICATION OF THE CAUSE OF DEATH.

To the Editor of THE LANCET.

SIR,—I quite agree with the remarks of Dr. R. R. Rentoul in your issue of March 25th. I have advocated the careful examination of the body by the medical man who has attended the patient before giving a certificate as to the cause of death, at the same time verifying death by certain tests which I have drawn up for that purpose and published. Our society drew up certain tests of death, and promoted a Bill to amend the law relating to Registration of Deaths and to Burials, presented by Mr. George Greenwood, and supported by Mr. Atherley Jones, Mr. Rowlands, and ordered by the House of Commons to be printed June 27th, 1912.

I am, Sir, yours faithfully,

J. BRINDLEY-JAMES,

Examiner-in-Chief, London Association for the Prevention of Premature Burial.

Barnes, March 30th, 1916.

PSYCHO-ANALYSIS.

To the Editor of THE LANCET.

SIR,—In a letter in THE LANCET of March 11th Dr. Ernest Jones says:—

I venture to add, without much fear of contradiction, that the statements made by more than one of your recent contributors, to the effect that they have seen many patients who have been harmed by psycho-analysis, do not refer to the patients of those who are psycho-analysts in the only legitimate sense of the word—i.e., those who have been competently trained in the subject.

This does not appear to me to be a scientific attitude of mind. Every benefit to mankind has a reverse side of possible evil, and although these chances of evil may be considerably lessened by experts in any method, a certain amount of harm is sure to accrue to a certain number of patients with regard to psycho-analysis, and it is surely a safer and more enlightened attitude to recognise the possibilities of evil and to keep on the alert to battle with the evils than to lull oneself into a false security by asserting that they do not exist. As a rule, the greater the beneficial possibilities of anything, the greater in proportion are its deleterious possibilities.

I am, Sir, yours faithfully,

Tonbridge, Kent, March 31st, 1916. C. F. STREETEN.

CHILDREN'S FRESH-AIR MISSION.—The annual meeting of the friends of the Mission will be held in Staple Inn Hall, Holborn, by the permission of the Institute of Actuaries, on Wednesday next, April 12th, at 4 P.M. Alderman Sir William H. Dunn will preside, and the following are expected to attend and speak in support of the Fund: Mrs. Scharlieb, M.D., Miss Fairbank, Mr. Ernest E. Wild, K.C., and Mr. W. Pett Ridge.

The War.

THE CASUALTY LIST.

THE following names of medical officers appear among the casualties announced since our last issue:—

Died.

Major F. C. Lambert, R.A.M.C., received his medical education at St. Mary's Hospital, London, qualifying in 1902, and joined the R.A.M.C. in 1904. He has been twice mentioned in despatches.

Captain J. T. Leon, R.A.M.C. (T.F.), was a student at St. Mary's Hospital, London, qualifying in 1895, and was in practice at Southsea prior to the war.

Wounded.

Captain M. Gross, R.A.M.C.
Captain A. Robb, R.A.M.C.

DEATHS AMONG THE SONS OF MEDICAL MEN.

The following sons of medical men must be added to our lists of those who have fallen during the war:—

Lieutenant V. C. Bruce, Gordon Highlanders, second surviving son of the late Dr. A. Bruce, of Ainslie-place, Edinburgh.

Sergeant A. R. Carter, Rhodesian Regiment, elder son of the late Deputy Surgeon-General R. W. Carter.

THE HONOURS LIST.

The *Military Cross* has been conferred upon the following medical officers in recognition of their gallantry and devotion to duty in the field:—

Captain Bernard Grellier, R.A.M.C. (attached to 10th Battalion, Royal Welsh Fusiliers).

For conspicuous gallantry and devotion to duty during operations when tending the wounded under heavy shell fire. He helped to dig out wounded men who were buried.

Temporary Captain Leonard Douglas Saunders, R.A.M.C. (attached to 10th Battalion Notts and Derby Regiment)

For conspicuous gallantry and devotion to duty. He tended the wounded under heavy fire, and finally evacuated them all with great skill and care. His clothing was torn by fragments of shell, and he was at work for 48 hours without a rest. This is the third time he has displayed great coolness and devotion to duty.

Temporary Captain Harry Vere White, R.A.M.C. (attached to 7th Battalion Lincoln Regiment).

For conspicuous gallantry and devotion to duty during operations when tending the wounded. His dressing station was repeatedly hit by shells, and he himself was severely knocked about several times, but for 36 hours he stuck to his work.

Temporary Lieutenant Reginald Peter Nutcombe Brickland Bluett, R.A.M.C. (attached to 8th Battalion Durham Light Infantry (T.F.)).

For conspicuous gallantry. He tended the wounded under heavy shell fire, and was continuously at work for 20 hours. Through his exertions they were removed to a place of safety, although the aid post was unapproachable owing to the enemy's shell fire.

Temporary Lieutenant John Alexander Harper, 52nd Field Ambulance, R.A.M.C.

For conspicuous gallantry when leading stretcher-bearers during operations. On one occasion, when three of his bearers were wounded, he went alone, under heavy shell fire, to the aid post.

The name of Staff-Surgeon R. B. Scribner, R.N., is mentioned in a dispatch by Rear-Admiral Sir Dudley de Chair for good services in the patrol cruisers.

FOREIGN DECORATIONS.

The President of the French Republic has conferred the Legion of Honour upon the following medical officers in recognition of their distinguished service during the campaign:—

Grand Officer.—Surgeon-General Sir A. T. Sloggett, K.C.B., C.M.G., K.H.S. (substituted for the "Croix de Commandeur," the award of which was reported in THE LANCET of Nov. 13th, 1915).

Croix de Guerre.—Lieutenant-Colonel J. Mill, R.A.M.C (T.F.); Captain J. A. Cullum, Canadian A.M.C. (attached to 28th Canadian Infantry Battalion); Captain E. D. Gairdner, R.A M.C. (T.F.); Captain G. H. R. Gibson, Canadian A.M.C. (attached to Headquarters, 1st Canadian Division).

THE ENROLMENT OF MEDICAL MEN.

The following statement has been published by the War Office as to the need for medical officers in the military services: it may be read as an appeal for immediate enrolment.

In order to maintain the supply of medical officers required to meet the needs of the military services, it is urgently necessary in the interests of the civil community no less than of our armies that all qualified medical men not exceeding 45 years of age, irrespective of their circumstances, should without delay enter their names under the Enrolment Scheme which has been established by the Central Medical War Committee and has the authorisation of the War Office.

The work of enrolment is carried out by three representative bodies of the medical profession known as the Central Medical War Committee for England and Wales, the Scottish Medical Service Emergency Committee, and the Irish Medical War Committee. It should be understood that enrolment does not mean that the medical man is at once called up for service in the Royal Army Medical Corps; he may never be called up, and in any case will not be called up until the proper time has come for his services to be accepted. The real purpose of the scheme is to secure that those doctors are selected for military purposes who can best be spared at the particular date and from the particular place, with due regard to the needs of the civil population, to the personal circumstances of the doctor, and to the requirements of the armies.

To carry out efficiently the comparative process necessary for an equitable distribution of the burden as it affects the medical profession and the civil population, it is evident that all doctors of suitable age should have offered themselves for service, quite irrespective of their particular circumstances, whatever these may be, so that a proper selection may be made by a body equipped with the requisite information from all parts of the country, and thus competent to make the necessary comparisons. The only alternatives are haphazard recruitment and arbitrary demand.

It is for these reasons that the War Office has officially recognised and now relies upon the Central Medical War Committee and the corresponding committees in Scotland and Ireland. These committees include representatives of the Royal Colleges of Physicians and the Royal Colleges of Surgeons, of the universities and medical schools, and of the British Medical Association, and have associated with themselves in their work representatives of the Government departments mainly concerned. The committees have an organisation of representative local committees in all parts of the three countries, from which they obtain local information and advice, and they work in daily contact with the various Government departments concerned.

Furthermore, for the purpose of considering and advising, through the Central Committee, on cases in England and Wales, having such special features as exist, for instance, in regard to the staffs of the metropolitan hospitals, a Committee of Reference has, with the approval of the War Office, been now established by the Royal College of Physicians of London and the Royal College of Surgeons of England, acting jointly.

Thus it will be seen that, in order to secure the desired result, that is to say, to obtain the medical officers needed for the army month by month with the least possible interference with the needs of the civil population and the least possible injury to the individual practitioner, it is necessary that every medical man under the age of 45 who does not hold a certificate of enrolment (or of provisional acceptance by the War Office) should enrol at once. Only in this way can the exigencies of the situation be fairly and efficiently met.

VACANCIES FOR MEDICAL OFFICERS.—Three medical officers are urgently required to complete the establishment of the 2/1st Highland Mounted Brigade Field Ambulance. Also a regimental medical officer for the 2/2nd Lovat Scouts. Full particulars regarding pay and duties can be obtained from Major Mowat, Officer Commanding, 2/1st Highland Mounted Brigade Field Ambulance, 49, Northgate, Beccles, Suffolk.—Interesting work for medical officers in the 3/3rd Home Counties Field Ambulance, R.A.M.C. Only two or three vacancies exist, and medical men desirous of joining this unit should make immediate application to the officer commanding, at the headquarters, "Frenches," Redhill.

OBITUARY OF THE WAR.

ROBERT FRANCIS HEBBERT, M.R.C.S. ENG., L.R.C.P. LOND.,

CAPTAIN, INDIAN MEDICAL SERVICE.

Captain Robert Francis Hebbert, I.M.S., whose death was announced recently as having occurred in the Persian Gulf, joined St. Thomas's Hospital in 1900 as a student, having received his school education at Malvern. He combined work with play, as he took the first and second year college prizes, qualified for the Cheselden medal for surgery, and played Association football and tennis for the hospital. On obtaining his diplomas in 1906 he joined the Indian Medical Service. He will be sadly missed by all who knew and worked with him at the hospital. He had only recently married.

PERCY HAYCRAFT BERRY, M.R.C.S., L.R.C.P. LOND.,

LIEUTENANT, ROYAL ARMY MEDICAL CORPS.

Lieutenant P. Haycraft Berry, who met his death in trying to rescue a drowning man at Barrani, Egypt, on March 10th, was 27 years of age. He was educated at Malvern, and King's College, Cambridge, where he took an honours degree in 1910 and entered Guy's Hospital the same year, qualifying in 1913. Subsequently he held the appointments of clinical assistant and assistant house surgeon at his own hospital, but was forced by the urgent calls of a general practice to help his father and to forego further appointments which he could have held in the ordinary course of events. He joined the Royal Army Medical Corps in May, 1915, as soon as he could be spared from the press of winter work, and was attached successively to the Cambridge Hospital, Aldershot, the hospital ship *Assaye* (during the Dardanelles operations), and finally to the Berks Yeomanry. A friend writes: "A keen sportsman, he gained his oar in the May races of 1908, and was one of the winners of the Browning Pairs in 1910; also he was an excellent horseman. Always keen on matters military, he derived his enthusiasm for cavalry work whilst a member of the Cambridge University Officers Training Corps. In all games he was not only a good loser but an excellent winner. He never allowed an unfailing cheerful nature to dull an unusually perceptive brain, but rather let it be the means of overcoming obstacles which proved drudgery to others. To those who knew him intimately an appreciation of his character is unnecessary; to those who did not, nothing could be more eloquent of the man than the official telegram giving particulars of his death. 'At Barrani, seeing man drowning, plunged off rock into heavy surf with all clothes on to rescue. Immediately big wave broke over him and he disappeared. Body found five hours later with large wounds head, apparently ante-mortem. Buried March 11th at Barrani with military honours.'"

JOHN WILSON, M.B., CH.B. EDIN.,

LIEUTENANT, ROYAL ARMY MEDICAL CORPS.

Lieutenant John Wilson, who was killed in action on March 9th, aged 29 years, was born in Armadale, Linlithgowshire. He was educated at John Watson's College and Edinburgh University, where he graduated in 1909. A friend writes as follows concerning his death: "A message was received that several men lay wounded in a central trench. Lieutenant Wilson at once volunteered to go to their assistance, although it was necessary to cross absolutely open ground, swept by the fire of the hostile trenches. He reached the wounded men, bandaged up those who most required it, and was on his way back to shelter when he was fired upon by the Germans from their front-line trenches. A bullet struck him just above the heart and he died in a few minutes. His colonel says that Lieutenant Wilson by his energy and devotion to duty had earned the appreciation of every officer and man in the battalion, and only ten days before had the pleasure of recommending him for the Military Cross. To his professional colleagues and friends the news of Lieutenant Wilson's death brought grief and horror. He was beloved by all who knew him, and to his *clientèle* his loss is irreparable. Genial and obliging in disposition, intelligent and industrious in the prosecution of his work, transparently honest and straight in all his relationships with others, he was a man whom it was good to know."

CHARLES STRICKLAND, L.R.C.P. LOND., L.R.C.S. EDIN.,

FLEET-SURGEON, ROYAL NAVY (RETD.).

MANY naval surgeons and St. Bartholomew's men of the early "eighties" will hear with regret of the death of Charles Strickland, which occurred after nine months' illness borne cheerfully with great patience. He entered the medical profession in 1880, rather later than most of his contemporaries, as he had been obliged to live for some time in South Africa on account of pulmonary tuberculosis, the disease which recurred last year. Strickland had a happy disposition, thoroughly enjoyed his life, and his genial nature made him a social success both at the hospital and in the services. When the war broke out he was Fleet-Surgeon at the Royal Marine Light Infantry Barracks, Forton. Soon after this he was placed on the retired list on account of age, but he remained at this post until ill-health necessitated sanatorium treatment. He died somewhat suddenly on March 25th, at the age of 56. His funeral, a naval one, took place on March 31st at the Highland-road Cemetery, Southsea.

THE LATE MR. H. S. LYLE.—Henry S. Lyle, who had been senior honorary surgeon at the Liverpool Cancer and Skin Hospital for some 24 years, died at his residence, Upper Parliament-street, Liverpool, on March 29th. He qualified as a Member of the Royal College of Surgeons of England in 1880 and earned a well-deserved reputation as a dermatologist in Liverpool. He was civilian medical officer to the 9th King's (Liverpool Regiment).

THE CENTRAL MEDICAL WAR COMMITTEE.

A meeting of the Committee was held on Wednesday, April 5th, at which the most important business transacted was the approval by the Committee of the formation of a Compassionate Fund, to be used for the benefit of medical men joining the military services. The Committee decided to ask the Council of the British Medical Association to consider the desirability of instituting such a Fund. No evidence was placed before the Committee, in a Memorandum which had been approved by the Executive Subcommittee, that any special fund would be needed, but it appeared from many indications that it was advisable that some scheme for its formation should be put into readiness. The Memorandum pointed out rightly that the heaviest tax might be upon those who are relatively well off and least likely to mention their position. The losses of men in consulting practice, for example, owing to heavy commitments in the matter of rent, might be considerable, while their practices, being of a personal nature, would suffer during their absence.

The Committee considered the statement recently published by the War Office with regard to the enrolment of medical men, and several speakers dwelt upon the necessity of ascertaining with accuracy the number of medical men who are available for enrolment, as only in this way can it be gathered what proportion of medical men have enrolled and how far the burden is being fairly distributed under the scheme. It was generally recognised that the scheme could only be persevered with if the percentage of enrolment was high, 75 per cent. being the lowest figure mentioned. It was pointed out in the Committee that the Navy also needed medical officers and might need more. The statement concerning enrolment issued by the War Office must to some extent be read as indicating the needs of the Navy, a matter upon which the two services will come to some agreement. The following resolution was adopted:—

The Committee will not proceed to call up practitioners under the Enrolment Scheme unless and until 75 per cent. of those medical men in England and Wales, who on Jan. 5th, 1916, were of military age and not holding a commission, have enrolled, or have since that date received a commission in His Majesty's Forces or a letter of provisional acceptance. Military age for this purpose means under 45 years of age.

The official correspondence with regard to the formation of the Advisory Committee of the Royal College of Physicians of London and the Royal College of Surgeons of England was placed before the Committee. The names of the members of the Committee were published in THE LANCET last week. Mr. Frederick G. Hallett, the secretary of the English Conjoint Examination Board, is acting as secretary of the Committee, and formally announced that the body had been constituted, that its meetings would take place at the Royal College of Physicians of London, and that the office of the Committee would be at the Examination Hall, 8 to 11, Queen-square, Bloomsbury.

THE MILITARY HOSPITALS IN ALEXANDRIA.—A correspondent writes as follows: "Profiting by the opportunity offered by a few days' sojourn in Alexandria I have visited some of the military hospitals which have been established there during the past 12 months. There are four 'general' hospitals. No. 15 is in a large school in the centre of the town; No. 17 is at Victoria, a seaside residential suburb, also in college premises; No. 19 occupies the splendid Deaconess Hospital buildings and some adjacent schools; while No. 21 is housed in the Ras-el-Tin barracks, Alexandria, hard by the Sultan's palace. In addition to these, No. 5 Indian Hospital and the Bombay Presidency Hospital occupy the Casino at Ramleh. In many cases these premises, capacious and well-equipped though they were before the war, were inadequate for the demands put on them, and various adaptations have been carried out. Perhaps the most remarkable of these feats are those which have been necessitated by the equipment of theatres. It is impossible even for the hardened pessimist to avoid a lively sense of gratification in realising what our much-criticised doctors and soldiers are capable of doing in such an emergency as this. But it is not the theatres only that afford evidence of thoroughness and care in the carrying out of so difficult a task. The wards, the X ray rooms, and the sanitary arrangements all bear unmistakable marks of the same spirit of thoroughness. When extensions beyond the walls of the original premises have proved necessary marquees have been widely used as overflow wards. Where so much excellent work is being done it would be invidious to make special mention of individual officers, but as certain hospitals have undertaken particular tasks it is perhaps permissible to remark upon the splint factory at No. 21 General Hospital, the venereal wards at No. 17, and the important researches into dysentery at No. 19. At all the hospitals surgery of a very high order has been practised, the records of which, when collated and digested, will prove of material value in the future. The other day a foretaste of this was afforded by the discussion which the Alexandria Clinical Society held at No. 17 General Hospital on the treatment of head injuries. This will probably be reported fully. The discussion, which was opened and closed by Colonel Sir Victor Horsley, was listened to by over 100 officers. It is, perhaps, in the department of medicine, however, that these hospitals have done their finest work. The arrangements for dealing with large numbers of dysentery and enterica cases are everywhere admirable, and the results both in regard to recovery and spread of infection have been most gratifying. The re-discovery of the value of emetine in amœbic dysentery by Sir Leonard Rogers was made in the nick of time, and has saved scores of lives. No Briton who has visited these hospitals could fail to be proud of their equipment, organisation, and actual performances."

Medical News.

EXAMINING BOARD IN ENGLAND BY THE ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—At the First Professional Examination of the Conjoint Examining Board held on March 28th, 29th, 30th, and 31st, and April 1st and 3rd, the following candidates were approved in the undermentioned subjects:—

Chemistry and Physics.—Alexander Herbert Bean and Hugo Boger, University College; Walter Richard Baxter Booth, Manchester University; Percy Croad Brett, St. Mary's Hospital; John William Chadwick, Manchester University; George William Chester, King's College; John Joseph Coghlan, London Hospital; Redgewell George Dansie, King's College; Ralph Martin Ealand, Bristol University; Mohammed Nour Eldin, St. Bartholomew's Hospital; Riad Akhnookh Fancus, Manchester University; James Hassall France (special); Werner Göthe, Middlesex Hospital; Thomas Hodgson Jordan Hargreaves, Royal Albert Memorial College, Exeter; Albert Reby Jones, Liverpool University; Thomas Trefor Jones, Manchester University; Reginald Oladipo Lahanmi and Reginald Cyril Lightwood, King's College; John Andrew Mackay-Ross, St. Bartholomew's Hospital; Edgar Duncan MacMillan, South-Western Polytechnic; Hussein Nosrat, University College; Leslie Penhall Phillips, King's College; Henry Christoffers Powell, Charing Cross Hospital and King's College; Johannes Jacobus Redelinghuys, University College; Thomas Roger Rees, University College, Cardiff; Mary Jane Ripley, University College; Jacques Spira, Brussels University and King's College; Edward Howard Strange, University College, Cardiff; Harold John Vane Sutton, Middlesex Hospital; John Christopher Twomey, Liverpool University; John George Walker (special); Albert Charles Zwaris Wijayaratne, University College; Tudor Williams, University College, Cardiff; and Charles Florance Young, London Hospital.

Chemistry.—Mark Louis Barst, London Hospital; Henry Leigh Bowen, King Edward's School, Birmingham; Maxwell Hall, Guy's Hospital; Reginald Rowley Halsall and David Hoole, Manchester University; John Dougan Kelson, London Hospital; Daniell Maximos, King's College; Edgar Lewis Jones Reason, St. Mary's Hospital; Constance Elizabeth Marlar Ridout, University College; Herbert Leyland Sackett, St. Bartholomew's Hospital; Mohamed Sidky, Middlesex Hospital; Samuel Snelson, Manchester University; and John Oscar Morgan Wade, University College, Cardiff.

Physics.—Douglas Robert Ainsworth and Hitchon Seater Chadwick, Manchester University; Harold Spencer Davies, University College, Cardiff; Mohammed Abdel Kader El Hennawy, St. Mary's Hospital; Sydney Hazeldine, University College; Montague Henry Lichtenstein, Manchester University; John Frederick Charles McColl and Elizabeth Esther McCulloch, Liverpool University; Oswald Edgar John McOustra, University College; Madeline Phyllis Parker, London School of Medicine for Women; Benn Roland Reynolds; University College, Cardiff; Josef Sonenberg-Bergson, Breslau University and King's College; and Sidney Bertrand Winnick, London Hospital.

Elementary Biology.—Charles Spencer Anderson, St. Mary's Hospital; Henry Edwards Archer and Douglas Albert Raoul Aufranc, Middlesex Hospital; George Frederick Baxter, Westminster Hospital and King's College; Ivy Constance Beach, London School of Medicine for Women; Alexander Herbert Bean, University College; Margaret Gladys Best, London School of Medicine for Women; Israel Blain, Manchester University; Hugo Boger, University College; Harold Bridgewater Bramley, Liverpool University; Ernest Brazao, Middlesex Hospital; Percy Croad Brett, St. Mary's Hospital; Mary Burfield, London School of Medicine for Women; Kenneth Entwisle Bury, St. Thomas's Hospital; Edward Joseph Jean Buyck, King's College; Louis Ely Reginald Carroll, St. Bartholomew's Hospital; John William

Chadwick, Manchester University; George William Cheater, King's College; Marion Constance Vera Clarke, London School of Medicine for Women; Alice Maud Mary Clegg, Technical School, Liverpool; Dudley Hugh Cockell, St. Bartholomew's Hospital; John Joseph Coghlan, London Hospital; Gerald Cecil Wootton Curson, Guy's Hospital; Redgewell George Dansie, King's College; Harold Spencer Davies, University College, Cardiff; Thomas Draper and Henry Dryerre, Royal College, Edinburgh; Robert Douglas Flintan, St. Thomas's Hospital; Harold Bert Flooks, University College, Cardiff; William Francis Gawne, Technical School, Liverpool; Barnett Goldfoot, St. Bartholomew's Hospital; Werner Göthe, Middlesex Hospital; Maxwell Hall, Guy's Hospital; Henry John Henderson, South-Western Polytechnic; John Herbert, Guy's Hospital; David Hoole, Manchester University; Francis Joselin Jauch, Birkbeck College; Henry Jennings and Silas Glynne Jones, Technical School, Liverpool; Thomas Trefor Jones, Manchester University; Henry David Kelf, Birkbeck College; John Dougan Kelson and Henry Alfred Connor Kite, London Hospital; Agnes Knowles, London School of Medicine for Women; Francis Knoyle, Birkbeck College; George Valentine Chapman Last, Technical School, Liverpool; Montague Henry Lichtenstein, Manchester University; Reginald Cyril Lightwood, King's College; Henry Davies Llewellyn, University College, Cardiff; John Andrew Mackay-Ross, St. Bartholomew's Hospital; Colin Campbell Mackinnon, Middlesex Hospital; Oswald Edgar John McOustra, University College; Cyril Randell Martin, Birkbeck College; Albert Edward Mills, Bristol University; James Aird Morton, St. Bartholomew's Hospital; Daniel Joseph O'Meara, Guy's Hospital; Leslie Penhall Phillips, King's College; Henry Christoffers Powell, Charing Cross Hospital and King's College; Mary Colegrave Prideaux, London School of Medicine for Women; Thomas Roger Rees, and Benn Roland Reynolds, University College, Cardiff; Constance Elizabeth Marlar Ridout and Mary Jane Ripley, University College; William Sleeman Roberts, St. Mary's Hospital; Edith Marjorie Rooke and Margaret Charlotte Scrace, London School of Medicine for Women; Ronald Cunliffe Shaw and Samuel Snelson, Manchester University; Edward Howard Strange, University College, Cardiff; Harold John Vane Sutton, Middlesex Hospital; Joseph Gillison Tait, Edinburgh School of Medicine; Thomas Ben Thomas, St. Bartholomew's Hospital; Norman Victor Wadsworth, Guy's Hospital; William Walsham, St. Mary's Hospital; John Stanley White, St. Bartholomew's Hospital; and Catherine Mabel Williams and Greta Isabel Yeoman, London School of Medicine for Women.

UNIVERSITY OF LONDON.—At examinations for internal and external students, held recently, the following candidates were successful:—

SECOND EXAMINATION FOR MEDICAL DEGREES, PART I.

John Vernon Cannadine Braithwaite and William Mark Brown, Guy's Hospital; Michael Waldo Boone Bulman, London Hospital; Leslie Burvill-Holmes, Guy's Hospital; Ernest Edwin Carter, St. Thomas's Hospital (distinction); Francis Cavers, University College; Alix Jeanne Churchill, London (Royal Free Hospital) School of Medicine for Women; Harris Cohen, University College, Cardiff; Hyman Solomon Cohen, London Hospital; Morris Cohen, Guy's Hospital; Simeon Moses Cohen, University College, Cardiff; Florence Edith Coombes, London (Royal Free Hospital) School of Medicine for Women; Daryll Cedric Corry, University College; Carl Knight Cullen, London Hospital; Beryl Dyer, London (Royal Free Hospital) School of Medicine for Women; Edwin Spencer Etheridge, University College; James Fanning, London Hospital; James O'Farrell Fletcher, St. Mary's Hospital; Raymond Eustace Ford, University of Sheffield; Reginald Stafford Foss, St. Thomas's Hospital; Dennis Herbert Geffen, University College; Edward Emile Delisle Gray, Guy's Hospital; Robert Handley Greaves, University of Sheffield; Dorothy Margaret Greig, Hilda Treloggen Haggett, Edith May Hall, Joan Margaret Redford Harris, and Eleanor Harse, London (Royal Free Hospital) School of Medicine for Women; Henry Lewis Heimann, University College; Christopher Langton Hewer, St. Bartholomew's Hospital; Gilbert Rashleigh Hull, St. Thomas's Hospital; Graydon Hume and Reginald Cyril Bell Ledlie, Guy's Hospital; John Neil Leitch, St. Bartholomew's Hospital; Horace Sharman Le Marquand, St. Thomas's Hospital; Henri Toussaint Levieux, Guy's Hospital; Gdal-Leizer Levin, King's College; Hyman Jacob Levy, University College, Cardiff (distinction); William Ernest Lloyd, St. Bartholomew's Hospital; Syed Francis Mahmood, University College, Cardiff; Charles Dundas Maitland, St. Thomas's Hospital; Ida Caroline Mann, London (Royal Free Hospital) School of Medicine for Women; Maurice Marcus, London Hospital; Grant Massie, Guy's Hospital; Kathleen Harding Matthews and Anna Miller, London (Royal Free Hospital) School of Medicine for Women; Richard Maurice Hoyle Newbery, St. Mary's Hospital; Sybil Gertrude Overton, London (Royal Free Hospital) School of Medicine for Women; Jal Pestonji Padshah, University College; Wilfrid Walter Payne, Guy's Hospital; Reginald Ernest Pleasance, University of Sheffield; Rowan William Revell, University College; William Arthur Richards, University College, Cardiff; Owen William Roberts, King's College; Samuel Rosenschein and Charles Herbert St. John, Guy's Hospital; Ruth Mary Scutt, Olive Ballance Sharp, and Katherine Jane Shaw, London (Royal Free Hospital) School of Medicine for Women; Gerald Maurice Joseph Slot, St. Paul's School; Sonia Straschun, London (Royal Free Hospital) School of Medicine for Women; Muriel Amy Sutton, University College; Vanda Patten Thomas, Ruth Catherine Townshend, and Norah Edith Trouton, London (Royal Free Hospital) School of Medicine for Women; Noël Sydney Bailey Vinter, St. Bartholomew's Hospital; and Evelyn Cecil Whitehall-Cooke, St. Thomas's Hospital.

SECOND EXAMINATION FOR MEDICAL DEGREES, PART II.

Lena Cecilia Adam, London (Royal Free Hospital) School of Medicine for Women; *†‡Gerald Victor Wright Anderson, University College; Loveday Shackell Banes and Annie Hardy Banks, London (Royal Free Hospital) School of Medicine for Women; Monty Baranov, University College; Mary Rushton Barkas, London (Royal Free Hospital) School of Medicine for Women; Anthony Blackstock, King's College; John Douglas Magor Cardell, St. Thomas's Hospital; Wilfred Bayley Christopherson, St Bartholomew's Hospital; Charles Eric Cobb, St. Thomas's Hospital; Doris May Collins, London (Royal Free Hospital) School of Medicine for Women; Hedley Chave Cox and Ralph Coyte, St. Bartholomew's Hospital; Joyce Emily Craggs and Nora Annie Crow, London (Royal Free Hospital) School of Medicine for Women; Thomas Morris Davies, St. Mary's Hospital; †Mary Day, London (Royal Free Hospital) School of Medicine for Women; Edwin Frank Deacon, Guy's Hospital; †Elizabeth Denniston and Lilian Mabel Fisher, London (Royal Free Hospital) School of Medicine for Women; Gerald William Thomas Hunter Fleming, University of Durham; Abraham Foner, London Hospital; St. George Bernard Delisle Gray, Guy's Hospital; Magdalena Augusta Hilda Hamel, London (Royal Free Hospital) School of Medicine for Women; †Albert William Holgate, University College; Henry Nevill Hornibrook and Marshall Jackson, St. Bartholomew's Hospital; Vasant Ramji Khanolkar, University College; Muriel Elsie Landau, Mary Kathleen Forsaith Lander, and Alice Lloyd Lloyd-Williams, London (Royal Free Hospital) School of Medicine for Women; Ernest Kenneth Macdonald, St. Thomas's Hospital; Janet McAllister McGill, Kathleen McCrie McKeown, Gladys Matthews, and Vida Sara Maxwell, London (Royal Free Hospital) School of Medicine for Women; Ludlow Murcott Moody, King's College; Edith Mary Ponsonby Morgs, London (Royal Free Hospital) School of Medicine for Women; John Ernest Nicole, King's College and Westminster Hospital; Marguerite Henrietta Pam, London (Royal Free Hospital) School of Medicine for Women; Rowland John Perkins, St. Bartholomew's Hospital; Dorothy Priestley Priestley, University of Leeds; Mary Millicent Prior, London (Royal Free Hospital) School of Medicine for Women; Ernest Frank Rabey, Middlesex Hospital; Edward Douglas Thomas Roberts, St. Thomas's Hospital; Hugh Thornton Rymer, King's College; Edward Jeffrey Samuel, King's College and Charing Cross Hospital; Solomon Nahum Senitzky, London Hospital; Bryan Buckley Sharp, St. Bartholomew's Hospital; Joseph Harold Sheldon, King's College; Charles Ernest Alan Shepherd, King's College and St. George's Hospital; Bertram Leslie Slater, London Hospital; Frances Minnie Spickett, London (Royal Free Hospital) School of Medicine for Women; Gilbert Patrick Staunton and Nai Synn, St. Bartholomew's Hospital; Khiam Soon Tan, University College; Stanley Roy Tattersall, St. Thomas's Hospital; Aubrey Leonard Telling, University of Leeds; Cyril James Thomas, St. Thomas's Hospital: Elsie Maud Vialck, London (Royal Free Hospital) School of Medicine for Women; Robert Lawrence Walker, St. Mary's Hospital; *Austin Darley Wall, St. Bartholomew's Hospital; Arthur Elston Ward, St. Thomas's Hospital; Eugene Wolff, University College; and Sydney Carver Woodhouse, London Hospital.

* Distinguished in Anatomy. † Distinguished in Physiology.
‡ Distinguished in Pharmacology.

N.B.—This list, published for the convenience of candidates, is issued subject to its approval by the Senate.

UNIVERSITY OF MANCHESTER.—At examinations held recently the following candidates were successful in the subjects indicated:—

THIRD M.B. AND CH.B. EXAMINATION.

A. B. Platt.

SECOND M.B. AND CH.B. EXAMINATION.

Elizabeth C. Davies, Ellis Pigott, Marie Wardman, and F. L. Whincup.

Physiology.—James Yates.

FIRST M.B. AND CH.B. EXAMINATION.

Part I., Inorganic Chemistry and Physics.—May Ashburner, Martha F. Barritt, May Blakiston, Vincent Chadwick, Margaret M. Corbold, J. W. Crawshaw, K. V. Deakin, Dorothy M. L. Dyson, A. M. El Aguizy, Evelyn A. Garnett, Olive M. Gimson Archibald Harris, Joshua Harris, Sylvia K. Hickson, J. H. G. Holt, Arthur Ingham, H. A. Lomax, Alexander Maude, W. E. Mitchell, Doris B. Norman, Emily M. Peach, F. L. Pickett, Harry Rosenthal, Gerald Sheehan, Annie E. Sommerhalder, Doris A. Taylor, H. W. Taylor, Soloman Wand, Robert Williamson, and J. B. Wright.

Part II., Biology.—Samuel Adler, Martha F. Barritt, Vincent Chadwick, F. A. van Coller, Phyllis M. Congdon, Margaret M. Corbold, J. W. Crawshaw, K. V. Deakin, Dorothy M. L. Dyson, A. M. El Aguizy, H. P. Fay, F. R. Ferguson, J. B. Fulton, Evelyn A. Garnett, Sylvia K. Hickson, Arthur Ingham, John Jacobs, Irma Jéhansart, Ernest Jones, H. A. Lomax, Alexander Maude, G. L. Meachim, W. E. Mitchell, Doris B. Norman, Emily M. Peach, Annie Rothwell, Gerald Sheehan, Florence G. Sherry, Annie E. Sommerhalder, Doris A. Taylor, H. W. Taylor, Mary I. Turner, Soloman Wand, Robert Williamson, S. J. Woodall, and J. B. Wright.

Chemistry.—F. R. Ferguson and J. N. Laing.

Physics.—F. A. van Coller, H. D. Preston, Florence G. Sherry, and Ethel D. Willis.

Botany.—E. L. Morgan and G. L. Taylor.

DIPLOMA IN PUBLIC HEALTH.

Harold Heathcote, M.D.

FIRST B.D.S. EXAMINATION.

Chemistry.—E. L. Morgan and G. L. Taylor.

DIPLOMA IN DENTISTRY (FIRST EXAMINATION).

G. H. R. Doman, G. F. Langford, and Norman Wood.

Chemistry.—Teresa Candon.

Physics.—A. L. Craggs, Frederick Torkington, and W. R. Williams.

DIPLOMA IN DENTISTRY (SECOND EXAMINATION).

Dental Mechanics.—Frank Lewis and Bertram Wilkinson.

Dental Metallurgy.—D. M. Barnes, Norman Filtcroft, R. L. R. Heelan, Frank Lewis, V. W. Morse, and Matthew Raeside.

DIPLOMA IN DENTISTRY (THIRD EXAMINATION).

R. A. Birkett, T. F. Healey, and James Kershaw.

UNIVERSITY OF SHEFFIELD.—At the Second M.B., Ch.B. Examination, held recently, the following candidates were successful :—

James Newlyn Gale (distinction in physiology), John Vickerman Mainprize, George Eldred Rae, John Ryan, Alice White, and Ethel White.

UNIVERSITY OF DURHAM: FACULTY OF MEDICINE.—At the Convocation held on March 25th the following degrees were conferred :—

Doctor of Medicine for Practitioners of 15 Years' Standing.—Hugh Basil Greaves Newham and Samuel Arnold Sittampalam.

Degree of Bachelor of Medicine (M.B.).—Arthur Farrell Renner Dove, Harold Kingston Graham-Hodgson, Ethne Haigh, George Irving, Arthur Edwin Raine, Alfred Smirthwaite, and Robert Welch.

Degree of Bachelor of Surgery (B.S.).—Arthur Farrell Renner Dove, Harold Kingston Graham-Hodgson, Ethne Haigh, George Irving, Arthur Edwin Raine, Alfred Smirthwaite, and Robert Welch.

Bachelor of Hygiene (B.Hy.)—Bloomfield George Henry Connolly (in absentia) and William Grant.

The following received the Diploma in Public Health (D.P.H.) :—

Bloomfield George Henry Connolly and William Grant.

The following received the Licence in Dental Surgery (L.D.S.) :—

Harold Armstrong Metcalfe, Douglas Edward Sayce, and Lawrence Somerville-Woodiwis.

UNIVERSITY OF ABERDEEN.—At the graduation ceremony on March 28th the following degrees were conferred :—

Doctor of Medicine (M.D.).—Archibald Douglas Pringle.

Bachelor of Medicine (M.B.) and Bachelor of Surgery (Ch.B.).—William Alexander, John Anderson, Mary Ann Chalmers, Arthur Joseph Hawes, Arthur Ambrose Hearne, Stanley Henry, Eva Constance Ironside, Burjorji Sorabji Kanga, Thomas Scott Law, *Robert Daniel Lawrence (second-class honours), Arthur Alexander Mackenzie, Charles Wattie Macpherson, William John Moir, *Arthur George Reid (second-class honours), †Thomas Ogilvie Robson, Albert Edward Barr Sim, and Forbes Simmers.

* Much distinction. † Distinction.

DUBLIN UNIVERSITY SCHOOL OF PHYSIC, TRINITY COLLEGE.—At the recent Hilary term examinations the following candidates were successful :—

PRELIMINARY SCIENTIFIC EXAMINATION.

Botany and Zoology.—George Ernest Sainsbury and Jacobus Frederik Van Staden.

Chemistry.—Falkland Litton Cary, Ivan Wakefield Beatty, Leo Vincent Clifford, and Richard Bernard Shaw.

Physics.—Maurice Nurock, John Lait, Janie Millar Cummins, Herbert Francis Mooney, William Bernard Joseph Pemberton, Robert Henry Mulhall Corbet, Doris Louisa Graham, Leonard Abrahamson, David John Browne, Francis Victor Small, Percival Israel Levitt, William James Alexander Russell, Robert Dormer, Christopher John Lawrence Brock, Robert Anthony O'Meara, Eileen Hilda Dowse, Elsie Hilda Burns, Mervyn Edmund McBrien, Edward Haslett Frazer, Thomas Donald Gordon, Patrick Joseph Healy, Isaac Levy, Charles John Shortt, Olive Baile, William Burton Fox, Joseph Ballantyne Maguire, James Alexander Smith, Basle Stuart Smyth, Moira Mary Brown, Richard Victor Dowse, Nora Griffith Samuel Wallace Jameson, James Joseph Patrick Kelly, William Theodore Micks, Eric Richard Murray, Frederik Wynand Pienaar, Henry Patrick Stack, Herbert William Strong, and Cecil Samuel Wilson.

INTERMEDIATE MEDICAL EXAMINATION.

Part I., Anatomy and Physiology.—Alewyn Johannes Vorster, Reuven Rosenkov, Cyril Daniel Brink, Jan Jacobus Gabriel de Kock, William Richard Burns Olive Gertrude Blackham, Henry Blundell Van der Merwe, William Bruce Briggs, and Lionel Wigoder.

Part II., Applied Anatomy and Applied Physiology—Harry Lee Parker, Victor Millington Synge, Crawford Law Wilson, Lindley Albertyn, Patrick Bernard Molony, Robert Meade Daly Devereux, Mary Christina Sheppard, Johannes Cornelius Fouche, William Leech Young, William Philp Elford, Wilfred Vincent Pellissier William Sweetnam, Ernest Edward Rollins, Kenneth Greer, Thomas Hugh Robinson McKiernan, Paul Herbert Shelley Smith, Thomas Bousefield Herrick Tabuteau, Eric James Lydon, William Alfred Shannon, Percival Atkin Dorm r, Leslie James Nugent, William Frederick Mc'onnell, Thomas Scannel McDonald, Jason Grant Bird, Ethel Marjorie Luce, Eric Stuart Ewing Mack, James Arthur William Cullen, Thomas Mulock Bentley, James Michael Hill, Daniel McElwee, Olive Gertrude Blackham, John Benson McGranahan, and Pieter Johannes Swanepoel.

FINAL MEDICAL EXAMINATION.

Part I., Materia Medica, Pathology, Medical Jurisprudence, and Hygiene.—Patrick Rock, Robert Wallace Nesbitt, Joseph Roland Brennan, Hirsh Brill, William James McClintock, Sydney Verner Furlong, Harry Banks, Andries Adrian Louw Albertyn, Arthur Isaac Steyn, Charles Perceval Chambers, Willem Petrus Lubbe, Crosbie Weir, Sidney Alfred Clark, Thomas Edward Hill, Fleetwood William Porter Sullivan (Materia Medica and Pathology), Michiel Christoffel Dippenaar (Pathology, completing examination), Millicent Hamilton-Johnstone (Materia Medica, Medical Jurisprudence, and Hygiene, completing examination), and Hastings Harley Molloy (Materia Medica, completing examination).

Part II., Surgery—Joseph Warwick Bigger, Thomas Lane, Charles Lewers McDonagh, Louis Blumberg, Millicent Hamilton-Johnstone, Mortimer McGee Russell, Eileen Gertrude Gwynn, and Frederick John Murphy.

Part II., Medicine.—Joseph Warwick Bigger, Robert Clement Burke Ramsay, George William Doran, John Thorp Westby, Millicent Hamilton-Johnstone, Eileen Gertrude Gwynn, and Rupert Gordon.

Part II., Midwifery.—Millicent Hamilton-Johnstone, Joseph Godfrey Bird, Frank Healy, John Thorp Westby, Sydney Verner Furlong, and Henry Stephen Campion.

DIPLOMA IN PUBLIC HEALTH.

Part I., Bacteriology, Pathology, Chemistry, Physics, and Meteorology.—Brian Dodwell Crichton.

Part II., Sanitary Engineering, Vital Statistics, Public Health, Hygiene, and Epidemiology.—John Robert Dunn Holtby, Marjorie Chapman, and Florence Colquhoun.

METROPOLITAN ASYLUMS BOARD.—A three months' course of lectures and demonstrations in hospital administration for the diploma in public health will be given at the North-Western Hospital, Lawn-road, Hampstead, N.W., on Tuesdays and Fridays at 5 P.M., beginning Tuesday, May 2nd. A similar course will be given at the Grove Hospital, Tooting-grove, Tooting Graveney, S.W., on Mondays and Fridays at 5 P.M., beginning Friday, April 7th. Medical men desiring to attend at either hospital are requested to send a fee of £3 3*s.* to the clerk to the Metropolitan Asylums Board, Embankment, E.C., giving their full name and address.

THE MEDICAL AND DENTISTS' REGISTERS.[1]—From the Medical Register, 1916, just issued, it will be seen that the total number of registered medical practitioners up to Dec. 31st, 1915 was 43,225, the corresponding figures for 1914 being 42,378. The average number of names added to the Register by registration for the last 24 years is 1284, and for the last five years 1265. In 1915 death accounted for the removal of 774 names, as compared with 761 in 1914. The total number added to the Register in 1915 was 1526, which includes 181 colonial and 88 foreign registrations. In 1914 there were only 36 names in the foreign list, and the increase is mainly due to the inclusion of Belgian practitioners owing to the situation created by the war. The Dentists' Register for 1916, also just published, contains 5453 names, as against 5426 in the issue for 1915. The 1916 list includes 4005 graduates and licentiates in dental surgery, 9 colonial licentiates, and 14 foreign dentists.

BRITISH FIRE PREVENTION COMMITTEE.—This committee has reissued its "Air Raid Warnings," as in many cases it has been found that recommendations made last year in the matter of simple fire precautions to meet air-raid fires are again being overlooked. Warning notices to which special attention may be called here are No. 10 for hospitals and No. 11 for convalescent homes and hostels. Warning for factories and works engaged on Government contracts is No. 16, and the farmers' warning in respect of hay-ricks, stacks, and farm produce is No. 14. For voluntary workers engaged on Red Cross and similar work warning No. 28 has been specially printed to meet the requirements of their workrooms, whilst those in charge of Y.M.C.A. huts and other institutes for soldiers and munition workers should obtain No 25. Warning No. 17A deals especially with the air-raid danger, and circulars No. 18A and No. 18B refer to the general air-raid question and the ordinary householder's aspect respectively. Special notices are issued for ministers of religion in charge of places of worship; for education authorities, headmasters and headmistresses of elementary and secondary schools; and for managers of theatres, music halls, and cinema houses. Requests for notices and circulars should be addressed to the Registrar, The British Fire Prevention Committee, 8, Waterloo-place, London, S.W.

THE Holborn Maternity Centre and Invalid Kitchen, of 75 Lamb's Conduit-street, W.C., held a Baby Show on Wednesday last of infants who had for at least three months previously attended the weekly consultations of Dr. Dorothea Colman at the centre. Fifty mothers brought their babies. The judging was in the hands of Dr. Harold Waller and Miss Hadden, of the Bloomsbury District Nursing Association, assisted by Miss Thomas, and the prizes were distributed by Mrs. Parker, the Mayoress of Holborn. The Maternity Centre, which is a voluntary one, and, except for the Local Government Board grant, dependent on voluntary aid, may feel proud of this public recognition of its usefulness.

CENTRAL MIDWIVES BOARD.—Special meetings of the Central Midwives Board were held at Caxton Hall, Westminster, on March 15th and 17th, with Sir Francis H. Champneys in the chair. A number of midwives were struck off the roll, the following charges, amongst others, having been brought forward: The midwife being in attendance at a confinement and the child suffering from inflammation of, and discharge from, the eyes, and continuing so to suffer, she did not explain that the case was one in which the attendance of a registered medical practitioner was required, as prescribed by Rule E. 20 (5); she discontinued her attendance at a time when the child was so suffering; the midwife being unable to take and record the pulse and temperature of patients in such manner as to comply with Rule E. 13; not keeping her register of cases as required by Rule E. 23. A midwife, notwithstanding her omission to visit a patient on three days during the puerperium, had entered false records of daily visits and of daily pulse and temperature. Although not present at the birth of the child, a midwife made and subscribed a declaration under the Registration of Births and Deaths Act, 1874, that the child was still-born; medical aid having been sought for the patient she neglected to notify the local supervising authority thereof, as required by Rule E. 21 (1) (a); being drunk at the time of the delivery; neglecting to remove the soiled linen, placenta, and other matters from the neighbourhood of the patient and from the lying-in room as soon as possible after the labour, as required by Rule E. 10; douching the patient in a negligent and dangerous manner, using an enema syringe and employing only a single basin for the purpose, and neglecting to provide for the cleanliness and comfort of the patient, as required by Rule E. 11. A midwife not taking with her to a confinement the appliances and antiseptics required by Rule E. 2; neglecting to disinfect her hands and forearms and to wash the patient's external parts with soap and water and to swab them with an efficient antiseptic solution, as required by Rules E. 3 and 7 (b); not being scrupulously clean in every way, as required by Rule E. 1; a child suffering from serious skin eruptions on and after the ninth day, the midwife did not explain that the case was one in which the attendance of a registered medical practitioner was required, as prescribed by Rule E. 20 (5), and she did not hand to the husband or the nearest relati e or friend present the form of sending for medical help, properly filled up and signed by her, in order that this might be immediately forwarded to the medical practitioner, as required by Rule E 19. The midwife being from time to time in contact with cases of infectious illness—namely, pemphigus neonatorum—she neglected to undergo disinfection of herself, her appliances, and her clothing to the satisfaction of the local supervising authority before going to another maternity case, as required by Rule E. 5, and she did not understand and employ the antiseptic precautions required by Rules E. 3 and 7.

MEDICAL SICKNESS, ANNUITY, AND LIFE ASSURANCE FRIENDLY SOCIETY.—The annual general meeting of this society was held at the offices, 300, High Holborn, London, W.C., on March 28th, Dr. F. J. Allan presiding. Dr. Allan in his address presenting the annual report said that since the war broke out the experience of all insurance corporations had been exceptional, but that the society had done during the year a good deal of new business, and had a net gain at the close of 70 new members, while a considerable proportion had increased their insurance for sickness benefit. Nearly £20,000 had been paid during the year to members in sickness and accident benefit. The committee, he said, now proposed the reopening of the annuity fund. On the foundation of the society an annuity fund was formed, but the terms were not found equitable, and this business was discontinued. The absence of an annuity fund being now felt to be a defect, Mr. S. G. Warner, F.I.A., had been consulted, and had drawn up a scheme. Holders of annuities would be given several options, and in the event of death or surrender before the age of 65 all the premiums paid, except the first, would be returned with simple interest at 3 per cent. per annum. Members holding annuity policies under the old tables could not transfer to the new proposal. Considerable depreciation had occurred in high-class securities, and investments if realised now would suffer a loss. At the quinquennial valuation the investments had to be valued at the prices then obtaining, and it was decided to establish an investments reserve fund, to which about £4000 had been added, and the surplus balance of the management fund is being kept in hand in case of emergencies. The death of Mr. Addiscott, who had acted as secretary since 1893, and, on retirement, as actuary, was referred to. The society also mourned the loss of Mr. G. A. Heron, one of its trustees, who took great interest in the work. It was not proposed to recommend anyone to fill the vacancy, as they already had four good trustees in Sir Dyce Duckworth, Mr. W. E. Hempson, Sir Victor Horsley, and Dr. Dawson Williams. The chairman then formally moved the adoption of the report, which was seconded by Dr. Major Greenwood and duly carried. The officers for the year, submitted to the meeting in a list, were elected *en bloc*.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

The Budget.

CONSIDERABLE additions to taxation are proposed in the Budget which Mr. MCKENNA, as Chancellor of the Exchequer, presented on Tuesday, April 4th. In regard to income tax, the proposals are that earned income up to £500 a year shall pay 2*s.* 3*d.* in the £, instead of 2*s.* 1 1/5*d.*, as at present. For incomes between £500 and £1000 a year the rate will be 2*s.* 6*d.* in the £. By successive stages the scale is carried up to 5*s.* in the £, which will be paid on earned incomes where the total income exceeds £2500. On unearned income the new scale will begin at 3*s.* on incomes not exceeding £300, and will rise by stages of 6*d.* to 5*s.*, which will be paid on incomes exceeding £2000. These charges are subject to the existing statutory abatements and allowances. The licence duty on motor-cars and motor-cycles is to be greatly increased. The present scale in the case of motor-cars ranges from 2 guineas up to 40 guineas, and on motor-cycles there is a uniform charge of £1. The Chancellor of the Exchequer proposes that the duty on cars not exceeding 16 h.p. will be doubled, and on higher power cars trebled. Motor-cycles not exceeding 4 h.p. will pay £2 2*s.*, and above 4 h.p. three-quarters of the duty chargeable on motor-cars of like horse power. Mr. MCKENNA also proposes taxes on amusements, railway tickets, matches, and mineral waters, and increased taxes on sugar, cocoa, coffee, and chicory.

HOUSE OF COMMONS.

WEDNESDAY, MARCH 29TH.

The Royal Commission on Venereal Diseases.

Mr. KING asked the Secretary to the Admiralty whether his attention had been drawn to the recommendation in the Report of the Royal Commission on Venereal Diseases that a man in the navy should not be discharged if suffering from any such disease; whether any legislation was required in order to enable effect to be given to that recommendation, and, if so, whether he was prepared to introduce such legislation.—Mr. MACNAMARA replied: I think my honourable friend will see that the questions raised in the recommendation to which he refers is one which will call for careful consideration. He is, of course, aware that the report was signed so recently as Feb. 11th, 1916, and was publicly circulated in the early days of the present month.

Mr. KING: May we be sure that it is to receive careful attention at once and not put off further?—Mr. MACNAMARA: The matter will be considered, but I can give no undertaking as to it.

Mr. KING asked the right honourable gentleman whether his attention had been drawn to the recommendation in the Report of the Royal Commission on Venereal Diseases that men joining the navy should be warned at the earliest possible moment of the grave dangers which venereal diseases involved, and that the warning should be formally repeated at intervals of not less than a year; whether the existing regulations provided for such warnings; and, if not, whether he would cause the regulations to be amended so as to secure that the recommendation of the Commissioners should be carried into effect.—Mr. MACNAMARA answered: The reply to the earlier parts of the question being in the affirmative, the last part of the question does not therefore arise.

Mr. KING asked the Parliamentary Secretary to the Local Government Board whether it was the intention of the Board to use its power under the Public Health Acts to supply drugs used in connexion with venereal diseases free to medical practitioners, as recommended in the Report of the Royal Commission on Venereal Diseases; and whether legislation was required to enable the Board to secure accurate statistical information as regarded the prevalence

of disease among persons receiving institutional treatment, as recommended in the Report of the Royal Commission, and, if so, whether it was his intention to introduce such legislation.—Mr. HAYES FISHER said in reply: I cannot say more at the present time than that the Report of the Royal Commission as a whole is under the consideration of the departments concerned.

Mr. KING: Has the right honourable gentleman considered whether a clause might not be added to the Local Government (Emergency Provisions) Bill which would bring the recommendations within the purview of the Bill?—Mr. HAYES FISHER: My right honourable friend will consider that.

Mr. KING asked the Home Secretary whether his attention had been drawn to the recommendations in the Report of the Royal Commission on Venereal Diseases with respect to the examination of prisoners; whether it was his intention to carry them into effect; and whether he would give an undertaking that no female prisoner or female person detained in a Borstal institution should be locally examined except by a woman doctor.—Mr. H. SAMUEL wrote in reply: The compulsory examination of all prisoners to the extent suggested by the Royal Commissioners would under present conditions be impracticable. These recommendations cannot be dealt with apart from the other proposals of the Commission, but the whole subject will receive careful consideration, and it is impossible at present to say what course may be taken with respect to prisons.

Medical Arrangements in Mesopotamia.

Sir JOHN JARDINE asked the Under Secretary for War whether steps would forthwith be taken to secure for the forces on the rivers Tigris, Euphrates, and Karun, in addition to medical and surgical requirements for the case of wounds, such drugs and appliances as had been proved useful in cases of plague, cholera, malarial fever, sunstroke, guinea-worm, and other diseases likely to occur in the approaching very hot weather in the deserts of Mesopotamia.—Mr. TENNANT replied: I can assure my honourable friend that all the resources at the disposal of the War Office, whether in personnel or in stores, have been offered to the Commander-in-Chief in India.

Uninoculated Men in the Army.

Mr. ANDERSON asked the Under Secretary for War whether he would issue instructions that recruits who objected to antityphoid inoculation were to be allowed leave in the ordinary way, providing they produced evidence from the medical officer of health for the district they intended to visit stating that the neighbourhood was free from typhoid fever.—Mr. TENNANT answered: The necessity of preventing the introduction of enteric fever into military camps is paramount, and this necessitates that leave shall be granted sparingly to men who object to inoculation. I do not think that the suggestion made in the latter part of the question provides sufficient safeguard that uninoculated men on leave will not bring back infection.

Health Conditions at Fovant Camp.

In reply to Mr. NIELD, Mr. TENNANT (Under Secretary for War) wrote: I have obtained a report from the medical officer at Fovant (Salisbury Plain) who states that no training ground there is in a condition even remotely approaching that of a muddy marsh, and that there in nothing in the condition of the training grounds that constitutes danger in any degree to the health of the troops. Four deaths occurred at Fovant last year—one from diabetes, one from nephritis, one from brain tumour, and one from bronchitis—but none of these was due to the condition of the training ground. Extensive drainage works are not necessary. Measures which have been taken will render the conditions of this training ground as good as obtains elsewhere. The ground at Fovant is good sandy subsoil and dries up remarkably quickly.

Insurance Benefits and Medical Evidence.

Mr. STUART-WORTLEY asked the representative of the National Insurance Commissioners whether it had been found that a woman insured in the Approved Society conducted by the Prudential Assurance Company, and receiving a weekly allowance as insurance benefit therefrom, could be deprived of that benefit by the individual decision of a referee appointed by the Prudential Company without previous knowledge of the case and without consultation or communication with her panel doctor; whether a woman thus deprived of benefit or otherwise treated with harshness could under No. 13 (30 b) of the Approved Society's rules be required, as a condition of obtaining redress or getting her case submitted for impartial inquiry, to deposit a sum which might amount to so much as £1, and in case of an adverse decision to forfeit the deposit and pay the whole of the expenses of the arbitration; whether along with the notice of deprivation of benefit any information was given to the insured person as to the existence of a right of appeal or the nature of the steps to be taken to bring about such appeal; whether the said Rule 13 was one of 48 rules which covered 72 pages of a printed book; and whether it was proposed to leave unaltered a state of the law which made benefits so precarious and redress so difficult to persons of small means from whom compulsory contributions had been levied.—Mr. CHARLES ROBERTS replied: It rests with the society of which an insured person is a member to determine, subject to the member's right of appeal, whether the facts of a given case justify the payment of benefit and medical evidence obtained in accordance with the rules is for the guidance of the society in coming to a decision. In the case of the particular society named in the question, I understand that where a member is required to submit herself for special medical examination under the rule referred to, steps are now taken to inform the doctor by whom she has been attended, and that where the matter is referred to a medical umpire, it is not the society's practice to require any deposit, although the payment of a deposit is authorised by the rule. I am also informed that in all cases in which payment of benefit is suspended on the report of a medical referee the member is now furnished with information as to the course which she may pursue if dissatisfied with the society's decision. The particulars given in the fourth part of the question are substantially correct. Copies of the rules are available to members on payment of a sum not exceeding 2*d*. As regards the last part of the question I am sending the right honourable gentleman a copy of a circular issued by my department in May last on the subject of procedure in disputes between societies and their members.

THURSDAY, MARCH 30TH.

The Health of Munition Workers.

Lord H. CAVENDISH-BENTINCK asked the Secretary to the Ministry of Munitions whether he was aware that the Health of Munition Workers Committee had recommended, in view of the increase of industrial disease and accidents in controlled establishments, that a sickness register should be kept, that provision should be made for the medical examination of all workers on their admission to the factory, that one or more trained nurses should be appointed, that a committee of workers should be entrusted with the duty of investigating every accident which occurred in their own workplace, that local dressing stations should be established in each workplace for minor injuries and a central dressing station for more serious cases, and that provision for organised medical treatment should be made in every munition factory; and what steps had been taken to carry out the recommendations of the committee.—Dr. ADDISON replied: My right honourable friend is about to issue to controlled establishments a circular containing a summary of the recommendations made in this and two other reports recently received from the committee. Active steps are also being taken by specially appointed officers of the Ministry to bring home to employers in certain factories the need for action on the lines recommended by the committee.

Medical Arrangements in Mesopotamia.

Mr. MALCOLM asked the Secretary of State for India whether Sir W. Vincent and General Bingley, being subordinate officers of the Government of India, had the power to examine and report upon the share borne by the military and financial members of the Viceroy's Council in planning and executing the Mesopotamian campaign and the shortcomings connected therewith; and, if they were precluded from so doing, would he appoint an independent commission to take the necessary evidence from the highest responsible authorities in India.—Mr. CHAMBERLAIN replied: The answer to both questions is in the negative. The inquiry is confined to the medical and hospital arrangements of the Mesopotamian campaign. I assume that it will embrace all matters relative to the sufficiency or otherwise of the provision made in India and Mesopotamia for medical personnel, stores, and appliances, also as to the organisation of medical relief and the arrangements for dealing with the sick and wounded in the field, at the base, and in transit to the base. I have issued instructions that the Commission should fearlessly ascertain and assign the responsibility for the breakdown of relief, whether individuals or the system are to blame. Until the Commission has reported I cannot say whether a further inquiry will be needed. The Viceroy has informed me that he has invited Mr. E. A. Ridsdale, Red Cross Commissioner, now *en route* from this country to Mesopotamia, to join the Commission as a member.

TUESDAY, APRIL 4TH.

Tuberculous Soldiers.

Mr. TENNANT (Under Secretary for War) informed Mr. R. MCNEILL that the arrangements in force were that soldiers who became medically unfit for further service from tuberculosis were not sent to their homes when discharged from the army. In the case of those who were insured under the National Insurance Act, arrangements existed with the National Insurance Commission by which men, if they desired, were sent to sanatoria. Similar arrangements existed with the Local Government Board for men who were

not insured, sanatorium treatment being provided as a special privilege.

Hospital Accommodation at Blandford Camp.

Mr. CAREW asked the Under Secretary for War whether he was aware of the insufficient hospital accommodation at Blandford camp, Dorset; whether recruits underwent a proper medical examination before they were called up for service; and whether information was sent to parents or friends when cases of dangerous illness occurred.—Mr. TENNANT answered: The hospital accommodation at Blandford is considered to be sufficient. Serious cases are conveyed by motor transport to Wareham, and, if necessary, to other hospitals. The answers to the second and third parts of the question are in the affirmative.

The Eyesight of Recruits.

Mr. TOUCHE asked the Under Secretary for War whether recruiting authorities were acting in accordance with instructions in accepting for general service men who were unable to see 6/60 with either eye without glasses.—Mr. TENNANT wrote in reply: The minimum standard of eyesight without glasses for general service is 1/4 of the normal in one eye and less in the other. Men with vision below this standard should not be accepted for general service.

Appointments.

Successful applicants for vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward to THE LANCET *Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, such information for gratuitous publication.*

FARRER, R. T., M.R.C.S., L.S.A., has been appointed Certifying Surgeon under the Factory and Workshop Acts for the Brighouse District of the county of Yorks, West Riding.

GRANT, J. DUNDAS, M.D. Edin., F.R.C.S. Edin., has been appointed Surgeon in charge of the Ear, Throat, and Nose Department of the New Zealand Military Hospital, Walton-on-Thames.

MAINS, J. H., L.R.C.P. Lond., has been appointed Certifying Surgeon under the Factory and Workshop Acts for the Clackmannan District of the county of Clackmannan.

MARTIN, ROBERT COLLINS, L.R.C.P. Lond., M.R.C.S., has been appointed Medical Officer for the No. 1 District by the Bristol Board of Guardians.

MORGAN, ALBERT THOMAS, L.S.A. Lond., M.D. Brux., has been appointed Public Vaccinator for the Ashley District by the Bristol Board of Guardians.

MORGAN, JOHN FREDERICK HENRY, L.R.C.P. Lond., M.R.C.S., has been appointed Medical Officer for the No. 2 District by the Bristol Board of Guardians.

Vacancies.

For further information regarding each vacancy reference should be made to the advertisement (see Index).
When the application of a Belgian medical man would be considered the advertisers are requested to communicate with the Editor.

BIRMINGHAM AND MIDLAND EYE HOSPITAL, Church-street.—Resident Surgeon.

BIRMINGHAM GENERAL DISPENSARY.—Resident Medical Officer, unmarried. Salary £250 per annum, with apartments, attendance, &c.

BRISTOL GENERAL HOSPITAL.—Casualty House Surgeon. Also House Physician. Both for six or three months. Salary at rate of £175 per annum each, with board, residence, &c.

BRISTOL ROYAL INFIRMARY.—House Physicians and House Surgeons. Salary at rate of £120 per annum, with board, apartments, and laundry.

BRIXTON INFANT WELFARE CENTRE, 56, Tulse Hill, S.W.—Female Medical Practitioner for Wednesday Afternoon Consultations.

BURNLEY, VICTORIA HOSPITAL.—Female House Surgeon. Salary £160 per annum, with residence, board, and washing.

BURY INFIRMARY.—Senior House Surgeon. Salary £250 per annum, with board, residence, and washing.

CAMBRIDGESHIRE ASYLUM, Fulbourn, near Cambridge.—Junior Assistant Medical Officer, unmarried. Salary £200 per annum, with board, lodging, washing, and attendance.

CHESTERFIELD AND NORTH DERBYSHIRE HOSPITAL.—Second House Surgeon. Salary £150 per annum, with board, apartments, and laundry.

DERBY, DERBYSHIRE ROYAL INFIRMARY.—House Physician and Casualty Officer. Salary £200 per annum, with board, residence, &c.

DONCASTER ROYAL INFIRMARY AND DISPENSARY.—House Surgeon. Salary £250 per annum, with board, lodging, and washing.

DUDLEY, GUEST HOSPITAL.—Assistant House Surgeon for six months. Salary £120 per annum, with board, residence, and washing.

EXETER, ROYAL DEVON AND EXETER HOSPITAL.—Senior House Surgeon. Salary at rate of £250 per annum, with board, apartments, and washing.

HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST, Brompton.—House Physician for six months. Salary 30 guineas.

LANCASTER, COUNTY ASYLUM.—Temporary Assistant Medical Officer. Salary 6 guineas per week, with board, apartments, washing, and attendance.

LEEDS PUBLIC DISPENSARY.—Female Resident Medical Officer. Salary £130 per annum, with board, residence, and laundry.

LIVERPOOL, HIGHFIELD MILITARY HOSPITAL.—Assistant Resident Medical Officer. Salary £300 per annum, with rations, apartments, &c.

LONDON HOSPITAL.—Two Vacancies on Assistant Obstetric Staff.

LONDON TEMPERANCE HOSPITAL, Hampstead-road, N.W.—Assistant House Surgeon for six months. Salary at rate of 120 guineas per annum.

NEW HOSPITAL FOR WOMEN, Euston-road.—Female Senior Clinical Assistant (Out-patient Department), Thursday afternoon. Also Female Clinical Assistants. Also Female Resident Medical Officer at House of Recovery, New Barnet. Salary £60 per annum.

NORTHAMPTON GENERAL HOSPITAL.—Two House Surgeons. Salary £150 per annum each, with apartments, board, washing, and attendance.

PUTNEY HOSPITAL, Lower Common, S.W.—Resident Medical Officer. Salary £150 per annum, with rooms, board, and laundry.

QUEEN'S HOSPITAL FOR CHILDREN, Hackney-road, Bethnal Green, E.—House Surgeons for six months. Salary £100 per annum, with board, residence, and washing.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—Examiners under the Conjoint Examining Board in England.

ROYAL FREE HOSPITAL, Gray's Inn-road, W.C.—Male and Female House Physicians and House Surgeons for six months. Salary £50 per annum, with board, lodging, and washing.

SHEFFIELD, JESSOP HOSPITAL FOR WOMEN.—Female Junior House Surgeon, unmarried. Salary £80 per annum, with board, residence, and laundry.

SHEFFIELD ROYAL HOSPITAL.—Honorary Ophthalmic Surgeon.

SHEFFIELD ROYAL INFIRMARY.—House Surgeon. Salary £100 per annum, with board and residence.

SOUTHAMPTON FREE EYE HOSPITAL.—House Surgeon. Salary £100 per annum, with board, lodging, and laundry.

THROAT HOSPITAL, Golden-square, W.—Resident House Surgeon.

VICTORIA HOSPITAL FOR CHILDREN, Tite-street, Chelsea, S.W.—House Surgeon. Salary at rate of £200 per annum, with board and lodging.

WARWICKSHIRE AND COVENTRY JOINT COMMITTEE FOR TUBERCULOSIS.—Resident Medical Officer for Bramcote Sanatorium, near Nuneaton. Salary at rate of £250 per annum, with board, &c.

WESTMORLAND CONSUMPTION SANATORIUM AND HOME, Grange-over-Sands.—Second Assistant. Salary £200 per annum, with apartments, board, and laundry.

WINCHESTER, ROYAL HAMPSHIRE COUNTY HOSPITAL.—Female Assistant House Surgeon. Salary £100 per annum, with residence, board, and washing.

Births, Marriages, and Deaths.

BIRTHS.

BIGGER.—On April 2nd, at Cairo, the wife of W. K. Bigger, Lieutenant, R.A.M.C., of a son.

CLARKE.—On March 28th, the wife of Lieutenant H. H. Clarke, R.A.M.C., of a daughter.

IREDELL.—On April 2nd, at Cumberland-terrace, Regent's Park, the wife of Dr. C. B. Iredell, of a son.

PARTRIDGE.—On March 28th, the wife of Victor Stanley Partridge, L.R.C.P. Lond., M.R.C.S., L.S.A. Lond., of Coldharbour-lane, S.E., Temporary Lieutenant, R.A.M.C., of a daughter.

ROBINSON.—On March 25th, at The Cottage, Blundellsands, the wife of G. Burton Robinson, Captain, R.A.M.C. (T.F.), of a son.

SPARROW.—On March 29th, at Essex-road, Watford, the wife of E. C. Sparrow, M.B., Temporary Lieutenant, R.A.M.C., of a daughter.

MARRIAGES.

DEVINE—MILES.—On April 1st, at Our Lady and St. Joseph's, Poplar, Major J. A. Devine, D.S.O., R.A.M.C., of Winnipeg, Canada, to Mary Hilda, only daughter of the late Henry Miles, of Liverpool, and of Mrs. Miles, of Cambridge-road, Southport.

HUNTER—CAPE.—On March 31st, in London, by licence, Captain Ronald Nelson Hunter, R.A.M.C., to Isabella, eldest daughter of Mr. and Mrs. J. Wilson Cape, of Carlisle.

LEECH—BARKER.—On April 3rd, at Leonard Stanley, Ernest Bosdin Leech, M.D. (of Manchester), Captain, R.A.M.C., to Mary, daughter of the late Rev. H. Walder, of Jamaica, and widow of Robert Barker, of Marple.

LUCAS—MCKAIL.—On April 3rd, at St. James's, West Hampstead, Captain Reginald Blockley Lucas, M.B., M.S., R.A.M.C., to Cecily Helen, only daughter of Mrs. John McKail.

MALLET—ALLEN.—On April 1st, at Stoke Church, Devonport, Lieutenant H. H. Mallet, L.D.S., Dental Surgeon to H.M. Forces, B.E.F., to F. Ethel Allen, elder daughter of Lieutenant-Commander J. H. Allen, R.N., and Mrs. Allen, of Stoke.

DEATHS.

LAMBERT.—On March 29th, died on active service, Major F. C. Lambert, R.A.M.C., aged 37 years.

LEON.—On March 30th, at Grove-road, Southsea, from cerebro-spinal meningitis, John Temple Leon, M.D. Lond., Captain, R.A.M.C.(T.), aged 50 years.

OWEN.—On April 2nd, suddenly, Samuel Walshe Owen, L.R.C.P., M.R.C.S., L.S.A., in his 66th year.

N.B.—A fee of 5s. is charged for the Insertion of Notices of Births, Marriages, and Deaths.

The following magazines, journals, &c., have been received:—British Journal of Dermatology, Journal of the Royal Army Medical Corps, British Journal of Inebriety, Proceedings of the Royal Society of Medicine, Practitioner, British Journal of Dental Science, Therapeutic Gazette, Journal of Nervous and Mental Disease, British Dental Journal, Revue d'Hygiène, &c.

Notes, Short Comments, and Answers to Correspondents.

VITAL STATISTICS OF BRITISH GUIANA.

A REPORT, prepared by Mr. George D. Bayley, Assistant Government Secretary, on the Blue-book of British Guiana for the year ended March 31st, 1915, has been presented to Parliament. It gives the population of the colony, as estimated at the end of 1914, as 309,938—161,417 males and 148,521 females. Calculated on the basis of these figures, the birth-rate for the year was 34·4 per 1000, as compared with 34·6 per 1000 in the previous year. The mean rate for the preceding five years was 30·7 per 1000. Amongst the several races representing the community the birth-rates per 1000 of population were as follows:—Portuguese, 27·4; Europeans other than Portuguese, 12·8; East Indians, 35·2; Chinese, 31·0; blacks, 33·7; and mixed races, 35·0. Of the births registered 39·9 per cent. were legitimate and 60·1 per cent. illegitimate. The death-rate was 24·5 per 1000 of the estimated population as compared with 24·2 in the previous year. The mean rate for the previous five years was 30·0 per 1000. The death-rate of each of the various races was:—Portuguese, 34·6; Europeans other than Portuguese, 12·2; East Indians, 25·3; Chinese, 28 6; blacks, 32·6; and mixed races, 20·9 per 1000 of estimated population. The deaths of children under 1 year of age numbered 1811, or 170 per 1000 births, showing a further slight decrease as compared with previous years. In this connexion it is noted that invaluable work has been done by the Baby Saving League, a scheme inaugurated by Lady Egerton (wife of Sir Walter Egerton, K.C.M.G., Governor of the Colony) to instruct mothers in the rearing and care of their infants.

The six principal causes of death throughout the colony during the past five years are given by the Registrar-General as follows:—Malarial and other fevers, 16·4 per cent.; bronchitis and pneumonia, 12·6; bowel complaints (including dysentery, diarrhœa, and enteritis), 11·3; kidney diseases, 8·2; phthisis and other forms of tuberculosis, 6·9; and diseases of early infancy (including infantile debility and icterus), 7·2. Enteric fever is notifiable, and in 1914 262 cases were notified, with 100 deaths. Antimalaria and antimosquito measures are being generally and gradually enforced, with visible signs of success. In 1906–7 33,748 cases of malarial fever were treated in the sugar estates' hospitals; at the end of 1914–15 the numbers had fallen to 8421. Quinine has been for some years sold at all the post-offices to the general public at cost price; it is also distributed at the sugar estates free to labourers. Prisoners, members of the police force, the inmates of the industrial school at Onderneeming and of the orphan asylum, and the attendants at the public institutions are also supplied by the colony with free quinine, and administration of quinine to school children is now adopted by 106 schools out of 227. Ankylostomiasis, which has engaged the attention of the medical department for several years, has considerably decreased on the sugar estates; this is attributed to improved sanitary measures and the erection of latrines. The International Health Commission (Rockefeller Foundation) has carried out an active campaign against this disease in the villages.

The hospitals and asylums were maintained during the year in an efficient condition. There are five public hospitals in the principal centres, and the outlying districts are served by dispensary hospitals. The immigration law also requires the maintenance of hospitals on every plantation on which there are indentured East Indian labourers, and those institutions are available for the treatment of emergency and pauper cases from the general community. There were 529 patients in the public hospitals at the beginning of the year, and 11,692 were admitted during the 12 months, the daily average being 484. There were 1431 deaths. In addition to those admitted to hospital, outdoor treatment was given to 39,357 persons. The daily average of inmates in the Lunatic Asylum was 770; 77 were discharged cured and 65 died. At the Leper Asylum there were 383 patients when the year began—263 males and 120 females—and during the year 88 were admitted.

AN IMPROVED LIFE-SAVING WAISTCOAT.

A PERFECT device for keeping an individual afloat in case of sudden immersion has yet to be invented, the various collars, belts, and waistcoats intended for this purpose having the defect of bulkiness, while in the case of apparatus needing inflation circumstances may prevent the necessary operation being performed in time to save the life of the wearer, and it is conceivable that the mechanism might fail at the critical moment. In order to overcome these difficulties a waistcoat has been designed which is less bulky than others of its kind. A demonstration of this apparatus, which is named the Ever-ready Life-saving Waistcoat, was witnessed recently by our representative at the swimming baths attached to the headquarters of the Young Men's Christian Association, Tottenham Court-road, W.C., when a swimmer and a non-swimmer, fully clothed and shod with heavy boots, who each wore the waistcoat, jumped or dived into the bath, and after a momentary submersion rose to the surface and floated in a semi-upright position with the head thrown somewhat backward. The waistcoat consists of two separate waistcoats, one superimposed on the other and joined in such a manner that a layer of air is kept between them, thus assisting the buoyancy of the article. The inner waistcoat consists of a single thickness of waterproof material cut to fit the wearer, while the outer waistcoat, which fits the body loosely, is made of two thicknesses of the same material padded with kapok. (Kapok is the silky white floss developed in the fruit buds of the white silk cotton tree and has a specific gravity considerably less than that of cotton.) The trials, which were eminently satisfactory, suggest that travellers and ships' officers will find the garment useful as a life-saving apparatus, but it might be found inconvenient by members of a crew for wearing while engaged in their ordinary occupations about the ship, and most people would probably find the waistcoat uncomfortably warm save in cold latitudes or in cold weather. It can be adjusted in 30 seconds. The waistcoat is sold by the Life-saving Devices Syndicate Limited, Basildon House, Moorgate-street, London, E.C.

SCIENTIFIC TERMINOLOGY.

BY the same post we received the following communications:—

A correspondent in Worcestershire writes: "The great scientific detective, Craig Kennedy, who is making the heart of the British public palpitate weekly at the picture houses, says in his 'book of words,' the 'Exploits of Elaine,' when describing some scientific apparatus: 'The idea had been suggested to me by the cystoscope, which physicians use in order to look down one's throat.'"

A correspondent in Canada writes that he recently had three scalpels ground by a local cutler and got a bill for "three scalping knives."

TREATMENT OF FIBRINOUS BRONCHITIS.

To the Editor of THE LANCET.

SIR,—I wonder if any of your numerous readers could give me a hint as to the treatment of fibrinous bronchitis? I have at present under my care a case which has resisted all ordinary remedies and vaccine treatment; and I shall be greatly obliged if anyone will tell me of some remedy which they may have found successful in the treatment of these distressing cases. I am, Sir, yours faithfully,

March 30th, 1916. M.B.

THE HOFFMANN-LA ROCHE CHEMICAL WORKS, LIMITED.

THIS firm, with works at Idol-lane, London, E.C., ask us to state that the Home Office has now withdrawn the warning it issued in October, 1915, against commercial houses in this country trading with the firm of F. Hoffmann-La Roche and Co., of Basle, Switzerland, of which the London firm is a branch. It appears that the warning was issued under a misapprehension as to the enemy status of the Basle firm, which is entirely Swiss, and unconnected with either Germans or Austrians.

A Manifestation.—The author has neglected to supply us with any name and address, so that we are unable to return his or her manuscript.

COMMUNICATIONS not noticed in our present issue will receive attention in our next.

METEOROLOGICAL READINGS.

Medical Diary for the ensuing Week.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Thursday, April 13th.

DERMATOLOGY (Hon. Secretaries—A. M. H. Gray, J. H. R. McDonagh): at 5 P.M.

Mr. J. H. R. McDonagh: The Rationale and Practice of Chemo-Therapy.

N.B.—Fellows and Members of other Sections are invited to attend and to take part in the discussion.

Friday, April 14th.

ANÆSTHETICS (Hon. Secretaries—F. H. Shipway, Ashley S. Daly): at 8.30 P.M.

Annual General Meeting.—Election of Officers and Council for Session 1916–1917.

Paper:

Dr. M. S. Pembrey and Dr. F. H. Shipway: Observations on the Influence of Anæsthetics on the Body Temperature.

Demonstrations:

Dr. F. H. Shipway: Apparatus for the Administration of Warm Anæsthetic Vapours.

Dr. Harold Low: Apparatus for the Intratracheal Insufflation of Ether.

Dr. F. H. Shipway: Apparatus for the Intratracheal Insufflation of Ether.

Captain C. T. W. Hirsch: Modification of Waller's Chloroform Inhaler.

HUNTERIAN SOCIETY, 1, Wimpole-street, W.

WEDNESDAY.—9 P.M., Adjourned Annual Discussion on the Relationship of the Medical Profession to the State and the Community. Dr. H. J. Cardale, Dr. B. A. Richmond and others are expected to take part, and Dr. F. J. Smith will reply.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East.

TUESDAY AND THURSDAY—5 P.M., Oliver-Sharpey Lectures:—Dr. M. S. Pembrey: The Development of the Regulation of Temperature. (Lectures I. and II.)

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.

Course of Lectures on the Anatomy of the Human Body, for First-aid and Ambulance Students (open to all members of ambulance companies and first-aid classes):—

MONDAY, WEDNESDAY, AND FRIDAY.—6.30 P.M., Prof. A. Keith. 4 P.M. to 7 P.M., Exhibition of Anatomical Preparations and Specimens in the Theatre on lecture days, and between 10 A.M. and 5 P.M. in the Hall of the Museum on the following day.

POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.

MONDAY.—2 P.M., Medical and Surgical Clinics. X Rays. Mr. Gray: Operations. Mr. B. Harman: Diseases of the Eye. Dr. Simson: Diseases of Women.

TUESDAY.—2 P.M., Medical and Surgical Clinics. X Rays. Mr. Addison: Operations. Dr. Banks Davis: Diseases of the Throat, Nose, and Ear. Dr. Pernet: Diseases of the Skin.

WEDNESDAY.—10 A.M., Dr. Saunders: Diseases of Children. Dr. Banks Davis: Operations of the Throat, Nose, and Ear. 2 P.M., Medical and Surgical Clinics. X Rays. Mr. Pardoe: Operations. Dr. Simson: Diseases of Women.

THURSDAY.—2 P.M., Medical and Surgical Clinics. X Rays. Mr. Gray: Operations. Mr. B. Harman: Diseases of the Eye.

FRIDAY.—10 A.M., Dr. Simson: Gynæcological Operations. 2 P.M., Medical and Surgical Clinics. X Rays. Mr. Addison: Operations. Dr. Banks Davis: Diseases of the Throat, Nose, and Ear. Dr. Pernet: Diseases of the Skin.

SATURDAY.—10 A.M., Dr. Saunders: Diseases of Children. Dr. Banks Davis. Operations of the Throat, Nose, and Ear. Mr. B. Harman: Eye Operations. 2 P.M., Medical and Surgical Clinics. X Rays. Mr. Pardoe: Operations.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY.—Clinics:—10.30 A.M., Surgical Out-patients (Mr. H. Gillespie). 2.30 P.M., Medical Out-patients (Dr. T. R. Whipham); Gynæcological Out-patients (Dr. Banister). 3 P.M., Medical In-patients (Dr. R. M. Leslie).

TUESDAY.—2.30 P.M., Surgical Operations (Mr. Carson). Clinics:—Medical Out-patients (Dr. A. G. Auld); Surgical Out-patients (Mr. Howell Evans); Nose, Throat, and Ear Out-patients (Mr. C. H. Hayton). Radiography (Dr. Metcalfe). 3.30 P.M., Medical In-patients (Dr. A. J. Whiting).

WEDNESDAY.—Clinics:—2.30 P.M., Throat Operations (Mr. C. H. Hayton). Children Out-patients (Dr. T. R. Whipham); Eye Out-patients (Mr. R. P. Brooks); Skin Out-patients (Dr. H. W. Barber). 5.30 P.M., Eye Operations (Mr. R. P. Brooks).

THURSDAY.—2.30 P.M., Gynæcological Operations (Dr. A. H. Giles). Clinics:—Medical Out-patients (Dr. A. J. Whiting); Surgical Out-patients (Mr Carson); Radiography (Dr. Metcalfe). 3 P.M., Medical In-patients (Dr. R. M. Leslie).

FRIDAY.—2.30 P.M., Surgical Operations (Mr. Howell Evans). Clinics:—Medical Out-patients (Dr. A. G. Auld); Surgical Out-patients (Mr. H. Gillespie); Eye Out-patients (Mr. R. P. Brooks).

THE THROAT HOSPITAL, Golden square, W.

MONDAY.—5.15 P.M., Special Demonstration of Selected Cases.

THURSDAY.—5.15 P.M., Clinical Lecture.

For further particulars of the above Lectures, &c., see Advertisement Pages.

EDITORIAL NOTICES.

IT is most important that communications relating to the Editorial business of THE LANCET should be addressed *exclusively* "TO THE EDITOR," and not in any case to any gentleman who may be supposed to be connected with the Editorial staff. It is urgently necessary that attention should be given to this notice.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this office.

Lectures, original articles, and reports should be written on one side of the paper only, *and when accompanied by blocks it is requested that the name of the author, and if possible of the article, should be written on the blocks, to facilitate identification.*

Letters, whether intended for insertion or for private information, must be authenticated by the names and addresses of their writers—not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or news paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale, and advertising departments of THE LANCET should be addressed "To the Manager."

We cannot undertake to return MSS. not used.

MANAGER'S NOTICES.

TO SUBSCRIBERS.

WILL Subscribers please note that only those subscriptions which are sent direct to the Proprietors of THE LANCET at their Offices, 423, Strand, London, W.C., are dealt with by them? Subscriptions paid to London or to local newsagents (with none of whom have the Proprietors any connexion whatever) do not reach THE LANCET Offices, and consequently inquiries concerning missing copies, &c., should be sent to the Agent to whom the subscription is paid, and *not* to THE LANCET Offices.

Subscribers, by sending their subscriptions direct to THE LANCET Offices, will ensure regularity in the despatch of their Journals and an earlier delivery than the majority of Agents are able to effect.

THE COLONIAL AND FOREIGN EDITION (printed on thin paper) is published in time to catch the weekly Friday mails to all parts of the world.

ALTERATION OF INLAND SUBSCRIPTION RATES.

OWING to the alteration in the Inland Newspaper Postal rate, the postage on each copy of THE LANCET will in future be 1*d.*, and sometimes 1½*d.*

The revised Inland Subscription rates are:—

One Year	£1 3 3
Six Months	0 13 8
Three Months	0 7 0

The rates for the Colonies and Abroad (thin paper edition) will be as usual:—

One Year	£1 5 0
Six Months	0 14 0
Three Months	0 7 0

Subscriptions (which may commence at any time) are payable in advance. Cheques and Post Office Orders (crossed "London County and Westminster Bank, Covent Garden Branch") should be made payable to the Manager, Mr. CHARLES GOOD, THE LANCET Offices, 423, Strand, London, W.C.

ADVERTISEMENT RATES.

ABSTRACT OF

The Lumleian Lectures

ON

ACUTE POLIOMYELITIS.

Delivered before the Royal College of Physicians of London on March 30th and April 4th and 6th, 1916,

BY FREDERICK E. BATTEN, M.D. CAMB., F.R.C.P. LOND.,

PHYSICIAN, CHILDREN'S HOSPITAL, GREAT ORMOND-STREET, AND NATIONAL HOSPITAL FOR PARALYSED AND EPILEPTIC, QUEEN-SQUARE, W.C.

ACUTE poliomyelitis has, during the last decade, spread in an epidemic form over the face of the globe, and considerable advances have been made in our knowledge of the disease. It is true that previous to 1905 small epidemics had occurred, but it is only since that date that it has had its present wide prevalence. During the last six years the experimental investigations of Flexner and his co-workers at the Rockefeller Institute, of Levaditi at the Pasteur Institute, of Leiner and v. Wiesner in Austria, and Roemer in Marburg, have thrown much light on the nature of the disease. A wider knowledge of the clinical manifestations has been gained, and the investigation of acute cases has rendered the pathological process more clear. It is my purpose to put before you in these Lumleian lectures the epidemiological, experimental, and clinical observations, and some points with regard to the treatment of the acute stages of the disease.

It is during the last five years that the disease has been recognised by the public health authorities in England as a definite specific fever, and notification has been adopted. The British Islands have suffered comparatively little during the epidemic periods. Although much has been discovered with regard to the nature of poliomyelitis, it has not yet been possible to apply that knowledge to its prevention, and much investigation still remains to be done, not only in the experimental but also in the clinical and epidemiological fields. The similarity which the pathological changes have to those of rabies raised the hope that the precautions which have been so successful in dealing with that infection might be able to control poliomyelitis; but the disease in its spread bears such a likeness to that of meningococcal meningitis that this is hardly to be expected. It seems unlikely that any effectual remedy, other than prevention, will be found for a disease which is so fulminating in its attack, and so destructive in its effects on the central nervous system.

The first lecture will be devoted to the epidemiology and pathology, the second to the experimental, and the third to the clinical consideration of the subject. The names which have been used and suggested for the disease are numerous; but that of "acute poliomyelitis" has now come into such general clinical use, and is also used to describe the nature of the virus, that it is inadvisable to attempt to replace it. All that is required is that "poliomyelitis" shall be recognised as one of the acute specific fevers, having a tendency to affect any part of the central nervous system, and giving rise to a variety of symptoms dependent upon the portion affected.

EPIDEMIOLOGY.

The history of the early epidemics of poliomyelitis, and its spread through Sweden and Norway and America were dealt with, and the evidence accumulated by Wickman with regard to the spread of infection by means of carriers along the lines of communication, roads, railways, &c. Certain factors were common to all epidemics—seasonal relationship, age incidence, and mortality—which commonly amounted to 11–12 per cent.

There have been earlier epidemics in Great Britain, and a considerable spread of the disease took place in Cumberland in 1910. In 1911 numerous epidemics were recorded throughout England, notably in Devon and Cornwall and the Eastern Counties. These were investigated by Dr. R. J. Reece, but no definite conclusion has been arrived at as to the mode of spread of infection.

In September, 1911, the Local Government Board made the disease compulsorily notifiable in London, and in September, 1912, for the whole country. For the years 1912–13–14–15 some idea can be obtained of its distribution throughout the community by consulting a series of maps; these show that the disease is distributed in a very irregular manner. A marked prevalence can be noted in the counties of Lancashire, Cheshire, Stafford, and Warwick during the years 1912, 1913, and 1914, and with a sharp decline in 1915. Northampton, Bedford, and Bucks suffered severely in 1912, but remained fairly free after that date. Gloucester and East Sussex, on the other hand, had a high incidence in 1915, neither of these counties being severely affected in the previous years. The number of cases notified during the years 1912–13–14–15 were 823, 736, 500, and 408 respectively. The mortality lay between 13 per cent. and 16 per cent., and the incapacity, owing to permanent paralysis, was about 50 per cent.

During the year 1913 an epidemic of poliomyelitis occurred in Barrow-in-Furness which was investigated by Dr. H. A. MacEwen, who noted that it was restricted to young children. It is known that Barrow-in-Furness suffered a severe epidemic of poliomyelitis investigated by Dr. R. P. Garrow in 1910. So the disease when it occurred again in 1913 fell upon a locality in which the susceptibles had been picked out by the former epidemic, and the population, except for those who had come into existence since 1910, had a natural or an acquired immunity. It would seem that the susceptible material of a population is fairly soon exhausted.

The study of maps illustrating the distribution of cases in the London area points to the fact that certain districts seem to have an exceptional incidence of the disease, but here again, as in the distribution about England, there is a considerable irregularity. The charts prepared from the notified cases of poliomyelitis during the past four years, both in London and England, show that the disease has pursued the even tenor of its way with the usual seasonal incidence. There is no reason to believe that its prevalence has been greater or less than it was in years previous to notification.

PATHOLOGICAL ANATOMY.

Most observers of the present day regard the essential pathological change which occurs in acute poliomyelitis as an inflammation of the interstitial tissue of the central nervous system. This view has only been arrived at by the careful investigations of numerous observers in every stage of the disease. The leading points in the history of advance in this branch of the subject were dealt with. In 1905 Wickman examined a number of acute cases and showed that the process was not limited to the spinal cord, but occurred in disseminated form in the medulla, pons, cerebrum, cerebellum, and membranes. The process is mainly interstitial and of the infiltrative lymphocytic type. Wickman considers that within the nervous system the inflammation travels along the perivascular lymphatics; the perineural lymphatics probably carry the infection from the site of inoculation to the cord.

The lecturer showed, by a series of specimens from the brain, medulla, and spinal cord, that in addition to the perivascular infiltration there was considerable infiltration round the ganglion cells, and that these cells were destroyed by neurophagic cells, some of the ganglion cells being entirely replaced by these. The posterior root ganglia and the soft membranes of the cord shared in the infiltrative process. Sections of the peripheral nerves also showed infiltration, and in the later stages degeneration. The changes in the muscle were such that some fibres had undergone complete degeneration, whereas others were normal.

EXPERIMENTAL POLIOMYELITIS.

In 1909 Landsteiner and Popper succeeded in transmitting poliomyelitis to two monkeys, but they failed to propagate the experimental disease beyond the first generation. Flexner and Lewis overcame the difficulty of propagation by substituting the intracerebral for intraperitoneal method, and were the first to transmit the disease through a series of monkeys. They, Levaditi, and others showed that the virus would pass the porcelain filter, that it withstood the action of glycerine and prolonged drying.

In October, 1913, Flexner and Noguchi published the method by which they succeeded in cultivating the organism of poliomyelitis on a special medium. The micro-organism consists of globoid bodies measuring from 0·15 to 0·3 micron in diameter and arranged in pairs. They showed that the

micro-organism fulfilled the conditions hitherto demanded for the establishment of a causal relation between an external parasite and a specific disease. The micro-organism exists in the diseased organs; it is capable of reproducing on inoculation the experimental disease in monkeys, from which animals it can be recovered in pure culture. Besides these classical requirements the micro-organism withstands glycerination as does the ordinary virus of poliomyelitis. Flexner and Noguchi, in conjunction with Amoss, carried the strain through 20 subcultures and proved that the final culture was pathogenic to monkeys.

The observers Kling, Pettersson, and Wernstedt, in Sweden, had the opportunity of investigating an epidemic of poliomyelitis in 1911. They obtained washings from the nose, the mouth, the pharynx and upper air passages and small intestines of a number of patients: (1) dead of the disease; (2) living cases; (3) abortive cases; and (4) healthy persons in contact with the infected individuals. With these washings filtered through a Heims filter they succeeded in infecting monkeys, and they showed that a larger number of individuals in all the above groups carried the organism.

The transmission of poliomyelitis by means of dead objects and flies has been investigated by Josefson, and Neustaedter and Thro investigated the dust of a room in which a case of poliomyelitis had been nursed. They succeeded after many failures in producing poliomyelitis in monkeys. Rosenau in 1912 demonstrated that poliomyelitis could be transmitted from monkey to monkey by means of the bite of Stomoxys calcitrans (stable fly), and this observation was confirmed by Anderson and Frost. Clark, Fraser, and Amoss in 1914 conducted a further series of experiments with stomoxys which gave wholly negative results, and a second series conducted by Anderson and Frost were similarly negative. The whole of the experimental evidence is strongly against the communication of the disease to man by flies.

Flexner, Clark, and Amoss found that a strain of poliomyelitic virus propagated in monkeys for four years displayed during that time three distinct phases of virulence. At the outset the virulence was low; but by animal passage it quickly arose to its maximum, the maximum was maintained for about three years, and without known change in external conditions, a diminution set in and increased until at the expiration of a few months the degree of virulence about equalled that present at the beginning of the passage into the monkeys. By resorting to the original specimen from which the virus was obtained a highly virulent strain was again produced. It is clear that the frequent and long-continued passage through monkeys finally brings about a depression of virulence, whilst preservation in a state of latency for a period equally great exerts no depressing action. The cycle of changes in virulence is correlated with the wave-like fluctuations in epidemics of disease, which also consist of a rise, a temporary maximum and a fall in the number of cases produced.

The pathological change found in the experimental poliomyelitis in monkeys agrees with those and is similar to those in man. Kling, Pettersson, and Wernstedt, however, have described changes in their experiments on monkeys which have no counterpart in man, and for this reason Flexner, Clark, and Fraser are unwilling to accept these cases as the result of poliomyelitis.

POLIOMYELITIS IN ANIMALS.

Most observers have failed to transmit human poliomyelitis to animals other than the monkey and the ape. During epidemic periods, forms of paralysis have been noted in colts, horses, fowls, pigs, &c, but none of these paralyses have been proved to be due to poliomyelitis. Roemer in 1911 succeeded in transmitting a disease like poliomyelitis through a series of guinea-pigs; but monkeys were not susceptible to this disease. MacGowan describes poliomyelitis in sheep suffering from "loupin-ill," and the changes in the central nervous system were similar to those found in poliomyelitis. Flexner and Clark described paralysis in a dog simulating poliomyelitis. They were not, however, able to transmit the disease to other dogs. Marks was able to transmit poliomyelitis through a series of young rabbits. The animals suffered from no paralytic symptoms, and their cord showed no pathological change; but monkeys inoculated from their organs developed poliomyelitis, so that it is clear that the disease can be propagated by rabbits.

SERUM DIAGNOSIS.

It has been shown that the serum of patients and monkeys who have recovered from an attack of poliomyelitis has viricidal properties, and it is possible to test the serum for these. This is accomplished by taking a 5 per cent. emulsion of the spinal cord containing the active virus and mixing it with an equal quantity of the serum to be tested. The mixture is kept at room temperature for several hours; it is then injected intracerebrally into a normal monkey. A control monkey receives the same quantity of virus. The control monkey becomes infected, the other remains free. Anderson and Frost by this method found in six out of nine suspected cases of abortive poliomyelitis that the blood serum was viricidal against the virus of poliomyelitis. The serum injected into animals has no preventive or curative effect. The sera of animals which are immune to poliomyelitis, such as the horse, &c., has no viricidal power either *in vitro* or *vivo*.

Numerous observers have tried the fixation of a complement method, and all agree that the use of an extract of organs containing the virus as antigen does not permit the discovery of antibodies in the serum or the cerebro-spinal fluid.

CLINICAL FEATURES.

The clinical features of poliomyelitis may be most varied according to the part or parts of the nervous system affected. The grouping on an anatomical basis suggested by Wickman is that which is most helpful to the clinical description of the disease. The groups are as follows:—(1) The spinal form; (2) the bulbar, pontine and mid-brain form; (3) the cerebral form; (4) the cerebellar form; (5) the neuritic form; (6) the meningitic form; (7) the abortive form.

The spinal form is the common manifestation of the disease, but the clinical variations in this form are considerable and they are not always recognised as manifestations of poliomyelitis. The ascending type (sometimes called Landry), in which the progress of the disease is not uniform but becomes arrested for some days and then after an interval of 2–3 or more days again starts its upward course, is an uncommon manifestation of the disease.

The involvement of the thoracic and abdominal muscles with complete collapse of one lung is a rare symptom, but local paralysis of part of the abdominal muscles is somewhat more frequent. *Complete transverse* lesions of the spinal cord are not commonly recognised as poliomyelitis, but such occur and give rise on recovery to a spastic paraplegia. If the lesion is situated in the cervical region the clinical picture may be loss of power and atrophy of the muscles of the hands and arms, with a spastic condition of the lower limbs. Netter and Levaditi have shown by the serum test that the blood of a patient who had recovered from such an attack possesses the properties for neutralising the virus of poliomyelitis.

Paralysis of the neck muscles without affection of the bulb or shoulder muscles is an unusual manifestation, and such weakness of neck muscles makes it impossible for the patient to walk. Unilateral paralysis of the diaphragm occurs. Instances of affection of the cranial nerves and of ocular paralysis associated with blindness were recorded.

Among the rare manifestations in the *cerebral form* is that of athetosis. This occurred in a child in whom the left arm and left side of face showed athetotic movement, associated with flaccid paralysis of the left and partial paralysis of the right leg.

The *cerebellar form* is characterised by the acute onset of ataxia.

The *meningitic form* is one of the most interesting groups of poliomyelitis, and one which frequently leads to an error in diagnosis. The meningitis is indicated by the presence of lymphocytic cells in the cerebro-spinal fluid. Certain cases, however, manifest symptoms of meningitis without any change in the cerebro-spinal fluid. Some of these cases show on pathological examination characteristic poliomyelitic changes in the brain. Cases illustrative of the various types were given.

The *neuritic form* is one which many observers are not willing to accept as occurring in poliomyelitis. If the presence and persistence of pain are taken as the evidence of neuritis it may be asserted that there is no justification for the title, but cases are described after an acute onset in which there is symmetrical affection of the peripheral muscles of the limbs with loss of sensation over the extremities.

The *abortive form* has been described in the countries where large epidemics have occurred, but few cases are recognised as such in England, as the disease has never become widely spread in an epidemic form.

Relapses in poliomyelitis.—Reference was made to the so-called "jump" case of poliomyelitis in which the disease is not steadily progressive, but remains stationary for a day or two and then rapidly advances a further stage; arrest may again take place followed by further advance. Relapsing cases differ from the above in that the patient improves in the interval, and then after some weeks fresh symptoms develop which may again clear up, and then a further relapse may occur.

Second attacks of poliomyelitis are very rare. The literature contains some three or more instances of such, but none of them are very convincing, nor will they bear critical investigation.

Cerebro-spinal fluid in poliomyelitis.—The examination of the cerebro-spinal fluid in poliomyelitis has yielded variable results. In some the fluid has been normal, in others there has been an excess of albumin with a moderate increase of lymphocytes, in others again a very large increase of these cells has been noted. The condition of the cerebro-spinal fluid has varied not only with the time after the onset of symptoms at which the fluid was examined, but also with the nature of the case, the cases with the most marked meningeal symptoms tending to yield the largest cell count. Those who have had the opportunity of studying the cerebro-spinal fluid in the pre-paralytic stage have noticed a high percentage of polymorphonuclear cells, but in the large majority of cases seen in England, when the paralytic signs are well developed, the cell count is always lymphocytic and usually not very high.

The diagnostic value of the examination of the cerebro-spinal fluid was discussed. A high lymphocytic count is present in the cerebro-spinal fluid, in infection by tubercle, syphilis, mumps, measles, infective conditions of the sinuses and ear diseases, and also in a group of cases with acute meningeal symptoms described and investigated by Gordon. Monkeys inoculated with an emulsion from the spinal cord and from the parotid glands from these cases were unaffected, the presumption being that the cases were not cases of poliomyelitis. The nature of the virus to which the death of these children might be attributed must remain doubtful.

Intra-uterine poliomyelitis.—The occurrence of poliomyelitis in the fœtus during intra-uterine life is very difficult to prove. Not a few cases come under observation in which the paralysis is stated to have been observed immediately after birth, and when the child has come under observation the clinical features have been those of poliomyelitis. Flaccid paralysis of one arm due to birth injury of the roots of the brachial plexus is not rare, and Dr. Herbert Spencer has shown that hæmorrhage into the grey matter of the spinal cord in children dying at birth or soon after delivery is not uncommon. Two cases are reported in which the extensive flaccid paralysis of the muscles, not only of the arm but also of the legs, made it probable that the lesion was situated in the grey matter of the cord. The cases clinically resembled poliomyelitis. The condition was stated to have existed since birth, and in one of the cases pathological examination showed the changes in the spinal cord were those commonly found in long-standing cases of that disease.

Herpes zoster in relation to poliomyelitis.—It is well recognised that herpes occurs not only in association with a localised paralysis in the same individual, but is also liable to be present in an epidemic form at the same time of year. Many examples of herpes zoster on the forehead and face in association with ocular paralysis are on record; others of cervical herpes with facial paralysis; others of limb or trunk herpes with limb or abdominal paralysis. Several instances of such cases are given. Griffon examined the cerebro-spinal fluid in 11 cases of herpes, and found more or less marked lymphocytosis in all. In childhood the simultaneous occurrence of herpes and poliomyelitis is rare, and one case is quoted in a boy aged 7 years. Nearly all the recorded cases of paralysis associated with herpes are in adults and in many cases in elderly people, and it seems certain that many of these cannot be attributed to the virus of poliomyelitis.

Poliomyelitis and a generalised vesicular eruption.—A rash sometimes accompanies poliomyelitis formed of small vesicles widely distributed over the trunk and limbs. The vesicles resemble a small chicken-pock.

TREATMENT.

Recognising that poliomyelitis is an acute specific fever, having an incubation period of 4–12 days, the patient should be isolated. The infectivity is very slight, and in hospitals it is not necessary to place the patient in a separate ward, bed isolation being sufficient to prevent the chance of infection. As the virus is known to exist in the nasal and buccal mucous membrane it is essential to pay careful attention to the discharge therefrom.

Serum treatment.—It has been shown experimentally that the serum of patients who have recovered from an attack of poliomyelitis has the power to destroy the virus *in vitro*, but that this immune serum has no power to prevent the development of the disease when injected simultaneously or after the virus has been injected. Flexner and Amoss have shown that intraspinal injection of an immune serum is effective when introduced in the pre-paralytic stage in delaying and preventing poliomyelitic infection in a monkey. This method of intraspinal injection of immune serum has been used with success by Netter in cases of poliomyelitis of the acute ascending variety. The method is as follows. Some 20–30 c.c. of blood are obtained by veni-puncture from a patient who has passed through an attack of poliomyelitis (the length of time after the attack is not important, for it has been shown that the blood preserves its antitoxic properties for several years). The serum is separated by allowing the blood to clot and by centrifugalisation. Lumbar puncture is performed on the patient, and an amount of cerebro-spinal fluid removed corresponding to that of the serum which it is proposed to inject—usually about 10 c.c. The serum is now slowly injected, and the bed of the patient tilted so as to allow it to gravitate cerebralwards, the injection being repeated daily for three to four days.

There is little or no difficulty in carrying out the treatment. The difficulty is to obtain an old case of poliomyelitis who has already been tested and given a negative Wassermann and who is willing to give the necessary blood at the same time as a suitable case of acute poliomyelitis presents itself for treatment. It is useless to carry out the treatment when the disease has already become quiescent, and the most suitable cases are those (1) presenting symptoms of an ascending or progressive poliomyelitis; (2) presenting meningeal symptoms; (3) (if the diagnosis can be made) in the pre-paralytic stage.

Since animals are immune to poliomyelitic virus, the possibility of employing the sera of animals has been considered; but Flexner and Lewis found that the sera of horses and rabbits had no viricidal action, sheep's serum was slightly active and might be increased by injection of the virus, but the degree of activity is small.

Rest.—There can be no doubt that rest is the most important factor in treatment: the too early movement may in some cases re-start the disease which has become quiescent. A child with an acute attack of poliomyelitis should be kept absolutely at rest in bed for at least three weeks. The principles by which physiological rest can be secured to the muscles were considered, and the conclusion arrived at was that the paralysed muscles must be put into the "zero position," a position defined by Mackenzie as the position in which the individual muscle itself is relaxed and both its own action and that of its opponents prevented. Sherrington has shown that postural contraction which counteracts the effect of gravity can be maintained for long periods without fatigue, and a position which can be maintained without fatigue must be a position of rest.

Posture.—Various methods have been adopted for keeping the affected muscles at rest. Most of them tend to immobilise the patients for many months. It is important whilst keeping the completely paralysed muscles in a normal zero position, and at rest, to encourage other muscles, which may have been more or less affected, to resume their normal function. This is accomplished by re-education. The erect position and walking are the best forms of re-education for the trunk muscles. The method of re-educating the severely paralysed muscles is described below.

Splints.—The practical application of the above principles has been carried out by placing the paralysed limb or limbs

in celluloid splints, accurately fitted to the limb *as soon as it is possible* to make the cast after the onset of the disease; as the splint is to serve in most cases not only for keeping the muscles at rest, but also as a support in walking, it is important that the position of the limb should be such that progression is possible. These splints were first used by Calot, and introduced into this country by Gauvain,[1] who has used them in the treatment of tuberculous joints.

The splint is moulded on a plaster-of-Paris cast of the limb, and it is the taking of this cast that is important; for the limb must be in the zero position, or, in other words, the position normally assumed to counteract the effect of gravity when the patient is in the erect position. That position, so far as the legs are concerned, is one of slight flexion of the knees with the foot at a right angle, or an angle slightly greater than a right angle to the tibia.

The advantages of this form of splint are:—(1) That they maintain the muscles constantly in a position of rest, for they can be worn day and night; (2) they do not immobilise the patient, so that walking exercise can be carried out without the liability to produce deformity or stretching of the muscles; (3) they are easily removed and replaced, so that other methods of treatment can be carried out; (4) no special boots or shoes are required.

Re-education.—In re-educating a severely paralysed muscle it is important in the early stages to place the limb in such a position that the load on the muscle is at its minimum, and only a very small force is required to overcome the effects of gravity. A bath is an excellent place to practise the re-education of badly paralysed muscles; for the weight of the limb is supported and ranges of movement are possible which without the support of the water are impossible. Walking exercises and the erect position are the best forms of re-education for the trunk and abdominal muscles. When once the legs are splinted it is possible to get the patient into the erect position, and such allows of the physiological use of the back, trunk, and pelvic muscles Such walking exercises are carried out by the use of a walking machine which supports the patient both physically and morally; for it is important to give the patient the feeling of complete security.

Other methods of treatment.—Other methods of treatment are by massage, electricity, and baths. The surgical treatment is not dealt with here.

Results.—During the last four years these postural and re-educational lines of treatment have been carried out in all acute cases with the result that very few deformities have arisen. Such as have occurred were due to the contraction of the flexor group of muscles at the hip.

Conclusion.—The adoption of the practice of placing the limb in a position of rest at an early stage of the disease will not only facilitate recovery but prevent the greater proportion of deformities now seen as the result of poliomyelitis.

[1] THE LANCET, March 4th, 1911, p. 563, and March 22nd, 1913, p. 826.

TRAGIC DEATH OF A MEDICAL MAN.—Mr. James Hamilton, L.R.C.P., L.R.C.S.Edin., L.F.P.S.Glasg., of Hayle, Cornwall, died suddenly on April 2nd in his motor-car, while on his round visiting patients; he was in his forty-eighth year, and leaves a widow and child.

LEICESTER ROYAL INFIRMARY.—The 143rd annual report of the Leicester Royal Infirmary (for 1915) is a record of excellent work accomplished under great difficulties. Leicester being the headquarters of the 145th Northern General Hospital, the honorary staff of the Infirmary were gradually requisitioned as the military hospital continued to be enlarged, and war service also absorbed resident medical officers and nurses. The number of beds made available for wounded soldiers was 160, while 200 were in use by civil patients. Some 400 recruits rejected from military duty by reason of physical disabilities received surgical attention and were subsequently enlisted. In addition many recruits received attention in the special departments of the Infirmary. In the civil wards 3082 adults were admitted and 674 children, as compared with 3264 adults and 657 children respectively in the previous year. In the military ward 692 patients were treated. In the out-patient department there were 4352 new cases and 10,004 old cases. Unfortunately, the expenditure shows an increase of £3240 on the previous year, the total for 1915 being £28,821.

A NOTE ON THE IMPORTANCE OF AUSCULTATION IN THE DIAGNOSIS OF THE VASCULAR INJURIES ACCOMPANYING GUNSHOT WOUNDS.

BY SURGEON-GENERAL SIR GEORGE MAKINS, K.C.M.G., C.B., F.R.C.S. ENG.,
CONSULTING SURGEON TO THE EXPEDITIONARY FORCE.

WELL-RECOGNISED and characteristic as are the murmurs produced by the existence of traumatic openings in the walls of the blood-vessels, yet the routine employment of the stethoscope for their detection seems hardly so generally adopted as should be the case. The importance of this method of examination is obvious in any class of wound, but it is especially valuable in the case of the multiple wounds inflicted by the various forms of fragments derived from the bursting of high-explosive shells and bombs. In these injuries one wound amongst a dozen or more superficial lesions may pass deeply into the body and cause a vascular injury, the existence of which may be readily overlooked by ordinary methods of examination.

A few examples illustrative of the value of the method may be opportune and of some utility.

(*a*) In a patient admitted with a compound fracture of the leg, the absence of pulsation in the posterior tibial artery behind the inner malleolus and in the dorsal artery of the foot indicated that both the anterior and the posterior tibial arteries had been divided. An exploration confirmed this assumption, and both vessels were ligatured. The further progress of the case was not satisfactory, and a rise of temperature, accompanied by fresh swelling of the calf, suggested that an extension of infection from the primary wound cavity was taking place. Auscultation of the limb revealed the presence of a loud systolic bruit over the course of the peroneal artery, and this vessel was cut down upon and ligatured above and below the wounded spot.

(*b*) A patient who had sustained multiple bomb wounds of the calf, after a short stay in France was transferred to England for further treatment. After a period of some months the man was passed again as fit for active service and returned to his regiment. Thence he was sent to hospital in consequence of swelling of his leg. Auscultation, probably employed for the first time since the injury was received, revealed the presence of a loud "machinery" murmur due to the existence of an unrecognised arterio-venous communication.

(*c*) A man received a wound from a fragment of shell which entering over the spine of the right scapula was retained in the body. On examination the fact that blood had been expectorated and that dullness existed at the right base suggested that a hæmothorax had developed. On examination of the chest a loud double murmur was audible over the entire præcordium, and this was conveyed to the left base. This murmur was assumed by the first observer to be cardiac in origin, but on further examination, a typical "machinery murmur" was detected below the right clavicle and an arterio-venous communication between the innominate vessels was diagnosed. The death of the patient from violent hæmoptysis the same night allowed this diagnosis to be verified, as also the absence of any valvular cardiac lesion.

These three instances serve to emphasise the value of this method of physical examination and to impress the fact that in any case of swelling of a limb in connexion with a gunshot wound the stethoscope affords a ready and certain means of establishing a diagnosis. Further, observation of the point at which the bruit is loudest and highest pitched will serve to localise the exact position of the lesion. The method is far more reliable than the uncertain practice of examining for the state of the distal pulse, for this is obliterated only if the vessel has been completely severed, or in the rarer instances in which large masses of hard clot exist to compress it, while diminution of size and force is more likely to be due to moderate pressure from without than to the existence of a lateral wound in the wall of the artery.

The third case (*c*) raises another question of some importance; although the local murmur could not have been overlooked during the process of examination of the chest to determine the presence of blood in the right pleura, yet the murmur was first detected in the cardiac region and thought by the observer to originate in the heart. Now,

the examination of a large series of arterial wounds has shown that in a very considerable proportion of the cases the local murmur, whether systolic if purely arterial in origin, or of the "machinery type" in arterio-venous lesions, is conducted to the heart. Further, that such bruits, although temporary, may persist for several weeks. The method of conduction would seem to vary according to the position of the vascular injury and the distance of the local lesion from the heart. In the case of injuries of an arterio-venous nature to the vessels of the axilla and neck, the murmur appears to be conducted by the whole mass of the tissues of the thoracic wall, and this view is supported by the observation that the normal heart sounds can readily be distinguished by the continuous roar audible over the whole cardiac area, the continuous roar preventing the discrimination of any abnormality in the systolic or diastolic periods. I have not met with any instance in which a pure arterial murmur in connexion with a wound of the vessels of the arm or forearm was audible in the heart, but I have noticed it in a carotid aneurysm, and in the case of wounds of the femoral vessels the condition is comparatively frequent.

When the murmur is conducted upwards from the lower extremity it appears to be conveyed by the column of blood in the vessels. In the arterio-venous injuries this is not surprising because the roar of the continuous murmur is always transmitted the more widely in a central direction. When, however, the bruit is due to a purely arterial lesion the circumstance is less likely to have been suspected, because in the majority of instances the pure systolic bruit is more freely transmitted along the limb in the peripheral direction. In spite of this fact, however, a systolic bruit, even not of a very loud character, may often be readily audible at the cardiac apex. The pure systolic murmurs are heard at the apex alone, but in one case of arterio-venous aneurysm of the thigh the double murmur was conveyed also to the base of the heart.

It may reasonably be asked why these transmitted murmurs are only of temporary persistence? The fact seems explicable on the ground that the existence of a gap in the wall of a large vessel gives rise to a very considerable disturbance in the heart's action. A certain degree of dilatation of the organ nearly always develops rapidly, the heart's apex reaching the nipple line or extending beyond it; its action is rapid; and some disturbance of the relative duration of the periods of systole and diastole occurs, the latter phase being somewhat prolonged. This disturbance tends to settle down when the patient is kept at rest in the recumbent position, and with its disappearance the transmitted murmurs also become inaudible. The cardiac upset is probably to be explained by the sudden alteration in the force required for the maintenance of the general circulation under altered conditions, and the view that an increased burden is placed upon the organ, even when a great vessel is only encroached upon to the extent of a portion of the contained blood needing to be circulated in a cavity of moderate size in communication with the lumen, appears to be supported by the fact that the peripheral blood pressure of the limb beyond the lesion remains persistently below the normal. Examination of a number of limbs in which such lesions existed has shown a difference of some 20 mm. of pressure measured by the sphygmomanometer, in fact a difference amounting to that which follows complete obliteration of the lumen by ligature of the vessel.

I have dwelt upon this question of the cardiac bruits, not because the presence of a conducted murmur can be of general use in diagnosis, in view of the fact that such an occurrence is not a necessary accompaniment of an arterial lesion. Still, the detection of an apical systolic murmur in a young healthy subject with an injury to the thigh might draw attention to the fact that a grave arterial lesion was present in the limb, and lead to its detection when the absence of local pulsation, together with the presence of free pulsation of the peripheral vessels, had led to the question of a serious vascular injury being placed aside.

MEDICAL MAGISTRATE FOR TORQUAY.—Mr. George Mitchell Winter, L.R.C.P. Lond., M.R.C.S. Eng., D.P.H. Cantab., the deputy mayor of Torquay, has been placed on the commission of the peace for that borough.

SHOCK[1] AND THE SOLDIER.

BY G. ELLIOT SMITH, M.A., M.D. SYDNEY AND ADELAIDE, F.R.C.P. LOND., F.R.S.,

PROFESSOR OF ANATOMY AND DEAN OF THE FACULTY OF MEDICINE IN THE UNIVERSITY OF MANCHESTER.

[*Note.*—Although I am wholly responsible for this article it is published with the knowledge and consent of Major R. G. Rows, R.A.M.C. I have to thank Mr. T. H. Pear and Mr. E. Gleaves for many suggestions and criticisms.—G. E. S.]

IT is generally admitted that never before in the whole history of war have the arrangements for the welfare of the soldiers been so well organised and on the whole so efficiently administered as those of our medical corps in the present war. Perusal of foreign medical journals makes it abundantly clear that the other combatants, not only our Allies, but also our enemies, have been closely studying all that we have been doing in this respect, and have not hesitated to benefit from our experience and to adopt many of our methods. It seems to me that we might follow their example much more than we have been doing, and in certain departments of medical work learn from them, or rather add their experiences to our own, in coming to a decision as to the best way of dealing with our own difficulties.

Among these the manifold problems relating to soldiers suffering from what may be designated by the vague and non-committal term "shock" (see footnote) are urgently calling for full consideration. These issues are of far-reaching importance and their solution involves matters of enormous difficulty. They concern not only the welfare of the individual patient, but also the maintenance of the efficiency of the combatant forces. In our system of selecting recruits the man with a varicocele or slight hernia is rejected, even though the greatest risk which accepting him would entail is the possibility that he himself might fail in an emergency. But no measures are taken to exclude the mental weakling, whose failure might lead to infinitely graver consequences, not merely to himself but to the whole of his unit. Even when the reality of such risks has been practically demonstrated by nervous breakdown, such men on recovery are still liable to be sent back to the firing line, in spite of what experience has now proved to be the certain knowledge that they will be useless as combatants, and will almost certainly succumb at the first strain.

But grave as these risks are, and urgently as they are crying out for remedial measures, there are other problems of this kind to be solved which will have a more profound and far-reaching influence upon the social—and, I may add, also the financial—welfare of the whole nation after the war.

There is no class of patients in the military hospitals concerning whom there is so much divergence of opinion as these, not merely as regards the methods of diagnosis and the mode of treatment that should be adopted, but also with reference to the wider questions as to what ought to be done with them after their discharge from hospital. This matter, therefore, is pre-eminently one concerning which it is desirable to obtain the reasoned views of competent and experienced men, irrespective of the side upon which they are serving.

Everyone who has had any dealings with the patients in the military hospitals scattered throughout this country must admit that much more might be done for patients suffering from some of the protean manifestations of "shock" than is being attempted at present. The general military hospitals contain scores of the milder shock cases, with which the medical officers have neither the time, nor, in many cases, the special knowledge, to deal. Such patients may recover of themselves without any attention, but a large number of them tend to get worse, and if they are left without attention their symptoms are apt to become stereotyped into definite delusions and hallucinations. Moreover, in a general hospital such men may become a constant source of disturbance and annoyance to other patients and to the nurses. One of the symptoms of their illness is a morbid irritability—they become upset and sometimes take offence at the merest trifles[2]—and this leads to trouble with patients, nurses,

[1] I am fully aware of the inadequacy and inappropriateness of this term, but the plain English word is less likely to give rise to misunderstanding or to involve me in the business of explaining terminological inexactitudes than the use of more technical language would entail.

[2] Major Rows: Mental Conditions following Strain and Nerve Shock, Brit. Med. Jour., March 25th, 1916, p. 441.

and the medical officers responsible for discipline. But if special consideration is shown them by the nurses the other patients are apt to misunderstand it, and even complain of favouritism. In other words, when mixed with wound cases in a general hospital, these nervous patients are apt to be regarded as a nuisance—which is bad for them and for the proper working of the hospital. Another consideration, also, is that the subjection of such men to the irksome regulations of military discipline, and the usual penalties for infringing them, is so potent a factor in producing disturbance as often to be quite fatal to any hope of amelioration. In a special hospital the wind can be tempered to the shorn lamb.

How is this situation to be remedied? In the other combatant countries, to judge from the medical journals, ampler provision has been made for dealing with this problem than has been done here.[3] The chief object of this communication is to set forth the views of some of those who have had to meet the infinitely vaster question of coping with the situation as it has presented itself to the medical corps in Germany and France, and incidentally, in the light of this knowledge, to urge that further efforts should be made in this country to deal with a problem which even here, where its magnitude is less, is one of great complexity and difficulty, the proper solution of which is becoming more urgent every week.

The men who are best equipped, both by their special knowledge and experience, as well as their present responsibilities, to deal with the matter, are for the most part much too busy dealing with the immediate practical issues to find time to consider or write about the wider questions with which I propose to deal here.

During last summer vacation I was allowed to take some small part in the work at the Military Hospital at Maghull, of which Major R. G. Rows has given a brief sketch[4] in the *British Medical Journal*. Living in the hospital with six officers who were devoting the whole of their time and energies to the diagnosis and treatment of soldiers suffering, for the most part, from mild forms of mental disturbance, even a few months of such intensive study gives one a very clear insight into the complexities and the enormous difficulty of the problems that have to be solved.

Nothing could be better calculated than such an experience to impress upon one the danger of publicly expressing opinions on the thorny questions of treatment, and the risks to which those who "rush in where wise men fear to tread" render themselves liable. Some explanation therefore is due at the outset for my venturing to break away from the attitude of discretion. For even the general consideration that questions of far-reaching importance are crying out for full discussion at the present moment is hardly a sufficient reason for a tyro to attempt to force the consideration of them upon the attention of the authorities and the medical profession.

On returning to university work at the beginning of the winter session, with the assistance of my colleague, Mr. T. H. Pear, I began to study the foreign medical journals that were available, for the purpose of comparing our short experience of these mental cases with that of the French and German medical officers. At the same time, mainly in response to numerous requests for information as to the nature of the work being carried on at Maghull, I was brought into communication, directly or indirectly, with medical officers working both in general and special hospitals in all parts of the country and abroad. This opened my eyes not only to the fact that there were considerable numbers of milder cases of "shock" scattered about in the general hospitals, but also that many medical officers, faced with the problem of treating such ailments, were anxious to learn something about their diagnosis and treatment, of which they frankly confessed themselves profoundly ignorant.[5] I have repeatedly been asked for enlightenment by general practitioners, suddenly called upon to deal with these specialised problems; and when they have been referred to authoritative statements,[6] it is customary for them to reply that they have neither the time nor the energy for the task of trying to understand the discussion of complex mental phenomena. It was the consciousness that a mere "outsider" like the writer might perhaps be able to draw a crude sketch more apt to appeal to such men than the statements of a specialist would be—even though he speak with more authority—which finally overcame my reluctance to undertake a task which so readily lends itself to misunderstanding.

Additional reasons for writing were, firstly, to call attention to certain statements in foreign medical journals, and, secondly, incidentally to raise for consideration some far-reaching general problems arising out of the question of these mentally afflicted soldiers. Without strong incentives such as these I should not have felt justified in attempting this task.

In coming to this decision I was also influenced by the remarkable position taken up by certain neurologists at the informal discussion of these cases of shock, which took place in London last November, under the auspices of the Medical Research Committee. One speaker made the remark that many of the patients suffering from shock "gave no history that threw any light upon their present condition," as though he expected that such men knew the causes of their illness, and would, in the course of a few minutes' chat, unveil the innermost secrets of their lives as readily and frankly as they would give the information that they had had measles.

The Importance of Diagnosis.

In the first interview with one of these patients, in the course of which the physician endeavours to obtain the details of the history of the trouble and makes the physical examination, it happens more often than not that he is unable to extract anything whatever that has any direct bearing upon the real causes of the illness. Even though the physician spends an hour or two in this preliminary cross-examination, in many cases no light is shed upon the patient's real history. In fact, many such prolonged inquiries may be made before any relevant information is obtained, and even then often the truth begins to emerge only after the patient's dreams have been obtained, either from his account of them or from inquiries as to the meaning of phrases shouted out during sleep.

In respect of such cases one often hears the comment made that the dreams are merely memories of incidents at the front. But if the trouble is taken to get a detailed record of dreams, in which every incident, however trivial and absurd it may appear, is noted, it will be discovered that in many cases the experiences at the front are blended with some episodes utterly alien to the war. If cross-examination of these incidents be conducted with patient persistence and discretion—and this is the kind of inquiry that does not demand any expert knowledge,[7] but simply common sense, discreet sympathy, and tact—it will very frequently lead up to some event in the patient's past history, the revivified emotions associated with which the war incidents have served to awaken, by stirring up similar emotions. By this simple process, if continued patiently day by day *by a physician who is striving to look at events from the patient's point of view*, the real reasons for the continuance of the shock symptoms are almost sure to be revealed. Without these means, and without such prolonged individual attention, the real nature of most of these cases is not likely to be discovered, and unless the causes are revealed the treatment cannot be other than empirical and fortuitous. I have repeatedly heard the argument that it is altogether unnecessary to attempt to diagnose such cases, and that isolation is the appropriate treatment for them, because Private X or Sergeant Y was so treated and made a perfect recovery. One might with equal cogency, or the lack of it, argue that it is unnecessary to diagnose a suppurating appendix as the cause of a case of peritonitis, because one has known of patients A and B who recovered after being treated with opium and the

[3] The reports published in the special war numbers of the *Revue Neurologique* (and especially Nos. 23, 24, November and December, 1915) bear ample testimony to the magnificent work being done by the French in this direction. Not only has special provision been made in each military district for dealing with neurological and mental cases, but also admirable reports upon the work are being published, and those responsible for the care of such patients have been afforded many opportunities for discussing their difficulties and learning one from the other.

[4] Op. cit., supra.

[5] It is a remarkable fact that Dr. Bernard Hart's excellent little book, "The Psychology of Insanity," which has had such a large circulation among the laity, seems to be almost unknown to the medical profession.

[6] Such, for example, as Déjerine and Gauckler's eminently sane and wise treatise, "The Psychoneuroses and Their Treatment by Psychotherapy," (Smith Ely Jelliffe's translation, second, English edition, 1913).

[7] Nor, contrary to the opinion expressed in a leading article in THE LANCET of March 18th (p. 627), any special vocabulary.

application of linseed-meal poultices. But just as no modern surgeon would regard the success of such individual cases as any excuse for not diagnosing and operating upon a suppurating appendix, so also the physician is not justified in arguing that correct diagnosis and appropriate treatment are unnecessary in cases of nerve shock.

But the question is constantly being asked, "How do you know when the *true* cause is discovered?" It is recognised by means precisely analogous to those by which a case of peritonitis is diagnosed to be the result of a suppurating appendix and not of pyosalpinx or any other lesion. The causal relationship between the symptoms and the history is, as a rule, so clear and indubitable that no one who has thoroughly investigated even a single case of "shock" can have the slightest doubt about the etiological nexus.

The Development of the Symptoms.

At the time when these notes were first drafted (November, 1915) hardly anything had been published in our medical journals on the subject of shock; and my aim was to compile a summary of the large series of most instructive reports that had appeared in the French and German journals. Since then, however, several important contributions to the discussion of this matter have been published in our journals. But though these articles simplify my task they do not affect the need for such a statement as I propose to make here.

In his vivid and sympathetic account of the phases through which officers pass when becoming neurasthenic, Dr. David Forsyth[8] called attention to the difficulties encountered in the past in defining "the nervous effects of intense emotional strain involving the risk of death," and how that after 20 years of discussion Bailey hit upon a means of escape from the clinician's dilemma by defining some of the cases as "mixtures of hysteria and neurasthenia."

Now, the fact does not seem to have been sufficiently emphasised that the terms "hysteria," "neurasthenia," "hypochondria," "mania," and "melancholia" are essentially labels given to groups of symptoms after they have become more or less stereotyped and systematised by each individual patient. In soldiers invalided from the front the physician has to deal, at any rate for the most part, with acute cases in which this process of systematisation has not gone very far. By labelling the outstanding symptoms "hysteria," "neurasthenia," "mania," or any of the rest of the terminological battery, there is a grave danger of overlooking the essential identity of the fundamental causes and nature of the trouble to be dealt with.

The many-sided manifestations of "shock" are in large measure determined by the inherited nature of each individual patient, but probably also, to an even greater degree, by his previous history and experience. In a not inconsiderable number of cases, however, the intensity and horror of the trauma are sufficient to explain the causation and to determine the form of the mental disturbance. As the culmination of months of mental strain and emotional stress, some terrifying experience indelibly imprints itself on the patient's mind and forces him to continue, day and night for weeks together, to see again and live through the awful moments; his attention remains wholly concentrated upon this experience, and he pays little or no attention to what goes on around him. If left to himself he will act in the way of all mankind and endeavour to interpret his feelings. Thus, if he continues to see visions of the scenes at the front, or to hear the sounds of bursting shells or the cries of his stricken comrades, he will explain these impressions to himself in accordance with his own experience and training. In other words, he will rationalise and systematise his new sensations until they become definite hallucinations and delusions, the precise form of which will be determined by the individual's previous history—i.e., by the way in which his accumulated knowledge and experience enable him to explain to himself and to interpret his new feelings. It is obvious that if such a patient comes into the hands of a physician before this process of rationalisation and systematisation has become established, the medical officer should be able to meet the patient's difficulties and help him correctly to interpret his unusual experiences. In this way the stereotyping of his erroneous interpretations—i.e., the development of systematised delusions or hallucinations—can be prevented.

[8] THE LANCET, Dec. 25th, 1915, p. 1399.

The Influence of the Individual's Life-history.

Even in such cases, where the culminating incident at the front has both started the trouble and determined its form, it is impossible wholly to exclude the influence of the individual's experience and life-history.[9] For in the procedure of rationalisation these are the sole sources of the knowledge made use of in this process, and therefore are mainly responsible for shaping his interpretations of his new experiences. Even before this stage is reached incidents in his past life, the memories of which are charged with a strong emotional tone, will influence the earlier after-effects of the terrifying experience at the front. Thus even in what seem at first sight to be straightforward cases of mental disturbance due directly, say, to shell concussion and the emotions associated with it, there is usually a definite link with the patient's previous experience. In most cases, however, this plays a much more obtrusive rôle. Let me cite a case in illustration of this, and I shall choose one to illustrate another point in addition—viz., that such troubles may develop without any shell concussion.[10]

A man, who had only recently been an inmate of a sanatorium, volunteered for military service at the outbreak of the war. After being at the front for about three months, during a most trying period of the campaign, he was sent to England as a case of neurasthenia. From his case-sheet little could be learnt except that he was subject to "dazed conditions." When seen in hospital he was suffering badly from insomnia; and the little sleep which came to him was constantly preceded by visions of two of his comrades who had been terribly lacerated alongside him. These hallucinations always seemed quite real to him at the time he experienced them, and aroused in him an intense fear that he was mad. It is important to notice that he was not subject to hallucinations during the day-time. Now, although these pre-sleeping experiences are of fairly common occurrence in the case of many normal individuals, they were novel to him, and they had begun to disturb him more and more seriously. He also had terrifying dreams, which regularly began with episodes at the front, and, without the interruption of awaking, changed as regularly into representations of sexual experiences, ending with seminal emissions. This latter fact, added to the bewilderment caused by his pre-sleeping visions, made him believe that he was insane, because it revivified a terror experienced when a boy from reading trashy literature.[11] These writings had convinced him, at the time, that he was going mad, because he had spermatorrhœa. The recurrence of these emissions, and of all that they implied to him, at the very time when he was suffering from pre-sleeping or "hypnogogic" hallucinations, had served to convince him that he was insane. He was in this condition when he came under treatment. It was first explained to him that hypnogogic experiences occur frequently in perfectly normal individuals. Examples taken from the writings of psychologists who have studied such phenomena, both in themselves and others, were used to illustrate this fact. Further, it was pointed out to him that his hallucinations did not occur except at the moment of falling asleep. The result of this talk was that although the images still presented themselves at night he was no longer afraid of them. By explaining to him in an elementary way the structure and functions of the

[9] The importance of the patient's past history has been stressed by Lieutenant-Colonel C. S. Myers in THE LANCET of March 18th, p. 608.

[10] In Dr. Forsyth's article, to which I have already referred, an admirable account has been given of the development of a condition when the patient's mental balance becomes liable to be upset by some trifling episode.

[11] In a very considerable proportion of these cases the literature which the patients had been studying, especially during adolescence, played a very obtrusive part in determining their present troubles. This applies not merely to pseudo-physiological works, but also to certain classes of books dealing with social and political problems. To me the extent of the influence of such writings has been a most amazing revelation. This subject is well treated in Stanley Hall's "Adolescence," vol. I., pp. 456-463.

It is very difficult to understand Dr. Forsyth's attitude (op. cit., p. 1400) in ascribing "the neurasthenia of civil practice" as "known to be the specific result of excessive onanism." In the cases that I have personally examined, or read about, it has been impossible to lay any of the blame on onanistic practices: but the terror which false teaching has inculcated regarding the effects of such practices has been a most lethal weapon in disturbing the equilibrium of many patients. The fact that much of this literature is the work of misguided cranks, who intend (or, at any rate, make the pretence of doing so) their writings to be warnings about the dangers of certain practices, makes them more potent instruments of destruction. Their very teaching is largely responsible for creating the dangers against which they pretend they are warning their victims. It is deplorable that nothing is done to combat the bad influence of this "literature."

Dr C. A. Mercier's characteristic protest (THE LANCET, Jan. 15th, 1916, p 154) against Dr. Forsyth's statement is no doubt quite justified; though, of course, in using it to attack the whole theory of the rational treatment of incipient mental disturbance he allows his facile pen to run away with him.

sexual organs, it was easily brought home to him that there was no truth in the false and pernicious literature he had been reading, but that his spermatorrhœa was a not unnatural incident in a man situated as he was. By discussing with him and explaining lucidly the nature of his disturbance, his condition was rapidly improved. He exclaimed, "Why wasn't I taught this when I was a lad; for then I should have been spared all this trouble." It was necessary for his medical attendant daily to talk to him and clear away his difficulties. But he relapsed again as the result of a quite trivial incident. Having leave out for an afternoon he went to the railway station to say farewell to his wife, who had been visiting him; she was taken ill at the station, and he accompanied her home; the result was that he was some hours late in returning to hospital, and was punished for it. The punishment of being confined to barracks is regarded by most soldiers as a purely military offence to which no moral stigma is attached. But in this man's case it produced the most profound depression and he talked of suicide. It was established afterwards that this attitude was due entirely to the exaggerated importance which in his condition of nervous instability he had attached to an early incident. It appears that when he was a child he was greatly upset by the fact of his father being sent to gaol. Because of this trouble the present trivial military offence assumed a special gravity in his eyes. He complained that he was tainted by his father. The nonsense written by some popular writers on heredity had led him to imagine that his present "criming" was due to the inheritance of his father's failing. This misconception being removed, the patient's condition improved immensely.

In such cases the full and frank discussion of disturbing factors such as this, and the clear exposition of the common-sense point of view, is immediately efficacious, and if persisted in regularly and conscientiously brings about a gradual and often rapid improvement.

This case illustrates how the continuance of the trouble may be due to incidents which in themselves might appear to an "outsider" to be altogether trivial and to have no connexion with the causation of the present illness. If full and patient inquiry is not made into such causes of disturbance, no treatment is likely to be efficacious: yet when discovered and explained, the patient's relief at once becomes apparent. This is not mere empty theory; but the common-sense point of view, of the truth of which every man's experience of the causes of his own moods should convince him. But in a still larger proportion of cases the necessity for unveiling the previous history of the patient becomes more insistent, because certain incidents in his past experience are responsible, not only for the persistence of his trouble, but also for determining the form his illness takes.

In many of the cases in which the shock-effects persist—and, of course, I am referring to those patients whose trauma is psychical—one important reason seems to be that the physiological expressions of the emotion excited at the time of the trauma—which expressions persist for a long time afterwards[12]—have served to link on to the present trouble other incidents in the individual's past history which were associated with similar emotional effects.

One of the chief difficulties in obtaining a general consensus of medical opinion in support of some definite scheme for dealing with these difficult problems is due to the fact that so many physicians refuse to admit the reality of the facts just stated. They claim that incidents which happened to a patient years ago can have no direct bearing on his present illness. It is inconceivable that such claims can be persisted in by any physician who has really investigated even a single one of these shock cases. The inquiry into the meaning of the symptoms links up the present condition with the past history in so definite and conclusive a manner that it is altogether incredible that anyone who has considered in detail the etiology of a case of shock could have any doubt whatever on the matter.

But in considering the symptomatology of these mental cases it must be obvious to everyone who gives the matter any consideration whatsoever that the manifestation of a severe psychical shock must necessarily be determined in large measure by the nature of the mind upon which the injury falls. The mental equipment of each individual consists largely of his personal experience, as interpreted and built up by himself into a system. When a man is subjected to a psychical shock one "structure" which is damaged is this systematised complex of the incidents of his previous history and the feelings and emotions associated with them, as they have been rationalised by him for his own satisfaction. It is idle to pretend, therefore, that the story of the patient's past experience can be left out of account, for it is the mind which is damaged, and the manifestations of the injury will obviously depend largely upon the individual's "mental make-up." There is still a widespread tendency (even in works on insanity and in the writings of psychologists) to speak of "hallucinations," "delusions," &c., as if they were diseases in themselves. A patient is described as "suffering from delusions" without any attempt being made to investigate the nature and genesis of these abnormal phenomena. But the formation of a delusion is an extremely complex process, usually occupying some time. Its basis is frequently a misunderstanding or set of misunderstandings which could be cleared away if detected early enough. The superficiality of speaking of a patient as merely "suffering from delusions" is clearly illustrated by Dr. H. Devine's memoir on "The Biological Significance of Delusions."[13]

But what is even more disastrous is to brand certain patients as "suicidal," and then to consign them to a single room without any real inquiry as to the meaning of this condition.[14] One of the reasons for this superficiality in treatment is the opinion (based upon a half-truth) that it makes the patient worse to talk about his hallucinations, and that one must rather try "to make him forget them." That it makes him worse to talk about them is sometimes true, but in these cases the disturbance so produced is usually temporary. On the other hand, many patients feel much better for having unburdened themselves in this manner.

The Relation of Correct Diagnosis to Treatment.

To suppose that without understanding the nature of and the specific reasons for the development of a hallucination one can "make the patient forget" his interpretation of a real experience, which has appealed to him day and night for weeks, or banish a delusion which is gradually becoming systematised and rationalised—i.e., intimately interwoven into the tissues of the whole of his experience—is an assumption which has no foundation in fact.

The point cannot be too much emphasised that many of these patients are quite sane, if conduct be regarded as the criterion of sanity; but they are growing afraid of the appearance of these abnormal phenomena, and take them for signs of incipient—or, more usually, perhaps of established—insanity. Two considerations arise from this—viz.: 1. Many of the troubles with which such patients are afflicted are not in any way indicative of insanity, though the patient thinks they are—e.g., the appearance of pre-sleeping hallucinations to a man who had always been accustomed, before the war, to fall asleep without such intense mental images Telling a patient who is worrying about such hallucinations that they often occur to quite normal people, explaining to him the way in which they may be supposed to develop, and accounting for his own particular experience, may be sufficient to clear away most of his mental trouble. 2. While treatment by isolation has obvious advantages in certain cases, in the particular group of patients which I am now discussing it is often dangerous, for it affords them every chance to brood upon and cultivate their initially mild derangements. As the presence of such mental phenomena is often confided to the physician only after great hesitation, and as such worrying experiences are common in cases of insomnia and other disorders, which, though troublesome, do not appear to be grave, it is possible that isolation may have serious effects in many cases in which its net results *seem to be* that the patient is merely no better.

The Real Trauma is Psychical, not Physical.

The majority of cases with which this communication is concerned is made up of men who, after spending months in the firing line exposed to every kind of discomfort and anxiety which modern trench warfare imposes, and having their deepest emotions repeatedly stirred up by the death of

[12] Mr. Pear tells me that according to a modern view of the emotions (that of Professor Külpe) they cannot be imaged, but are actually *reinstated* when the experience originally connected with them is recalled in memory. Whether this be generally true or not, it is obvious that thinking about a past experience which has been connected with a vivid emotion is frequently sufficient to bring about the emotion, even if in a mild form; and clearly the experiences which these soldiers recall in memory have frequently aroused emotions considerably more intense than those which occur to the average civilian.

[13] Journal of Mental Science, lxii., p. 256.

[14] Further, it is often not quite clear, when the word "suicidal" is used, whether it is intended to mean that the patient has contemplated or spoken of suicide, or has been known actually to have attempted to take his life.

comrades and the repeated reminders of their own peril, were struck down by "shell concussion." Gaupp defines this term as the general injury of the soldier in whose vicinity a shell has burst without wounding him. All direct bodily wounds produced by parts of a shell, or by objects thrown about by the explosion, are excluded from consideration in this connexion, although, of course, not infrequently the victims of "shock" are physically wounded also.

It is beyond the scope of this article to discuss to what extent slight injuries of the nervous system, or, in fact, of any part of the body, may be responsible for suggesting the form assumed by the so-called "functional" troubles with which I propose to deal. There is evidence to suggest [1] that trivial and transitory physical damage, as well as incidents in the individual's personal experience that were associated with powerful emotions, even many years previously, play the chief part in determining the form his present mental disturbance assumes. But in other cases the culminating experience at the front was of so terrible a nature as to be of primary importance, not only as the causal agent, but also as the determining factor in the production of a given symptom-complex.

It would be a great mistake to imagine that in all cases shell explosion is the exciting cause of the trouble. A considerable number of the patients have not been under fire. Some of them have not even gone to the front. Even though their experiences in the army or thoughts of what might be in store for them in the trenches may have played a considerable part in starting their trouble, I do not propose to discuss such cases here. Nor do I intend to consider the problem of what part, if any, war experiences may have played in hastening the onset of general paralysis or in stirring up mental trouble in patients who had previously been inmates of asylums.

But there is a very interesting and important class of patients which ought not to be omitted even in such a hasty survey as this. I refer to men who have stood the strain of trench life and hard fighting for months, or even more than a year, who have been wounded, "gassed," or buried, without any obvious mental trouble ensuing, and who then suddenly break down when resting.

A typical case is that of a non-commissioned officer who went through the first 11 months of the war in France and Flanders, was subjected to every kind of strain, physical, mental, and moral, which that stricken field provided; and in addition was wounded twice, "gassed" twice, and buried under a house, on all five occasions being treated in the field ambulance and then returning to the trenches. After all this experience he had not qualified for sick leave, but was granted five days' ordinary leave to return home, apparently in a good state of health. After reaching the homeland, and while waiting for a train in the railway station, he suddenly collapsed, became unconscious, and for months afterwards was the subject of severe neurasthenia. Apparently at the front the excitement and his sense of responsibility, and especially the example he felt that he should set his men, seemed to have kept him right. This stimulus removed, he broke down. The whole of his trouble seemed to be due to the dread lest, on his return to the front, the added responsibilities which would fall upon his shoulders (because most of his own officers had been killed and there would be new men to replace them) might be too much for him. His intelligence seemed (to himself) to have become numbed by his experiences, and he became conscious of the unreliability of his memory and of his inability to understand complex orders, or, as he put it, "even the newspapers." It was this that excited in him the dread lest he should be incompetent adequately to discharge the duties which would fall upon him. There was nothing of malingering or shirking in his case. There was no fear of physical injuries or of returning to the front; on the contrary, he was anxious to go back. His fear lest the possibility of his failure would be bad for the platoon was wholly due to that remarkable emotion of regimental loyalty, which comes out so strikingly in the nervous troubles of the non-commissioned officer.

This class of case demands a great deal of patient and sympathetic attention before the real cause is elicited, and then months of daily re-education to build up anew the man's confidence in himself.

(To be concluded.)

[1] See, for example, Roger Dupouy, "Notes Statistiques et Cliniques sur les Troubles Neuro-psychiques dans l'Armée en Temps de Guerre," Annales Medico-psychologiques, October, 1915, p. 444.

A STANDARD METHOD OF TESTING ANTISEPTICS FOR WOUNDS, WITH SOME RESULTS.

BY W. D'ESTE EMERY, M.D. LOND., M.R.C.S. ENG., L.R.C.P. LOND.,

CAPTAIN, R.A.M.C. (T.F.); DIRECTOR OF THE LABORATORIES, KING'S COLLEGE HOSPITAL.

ONE of the most astonishing medical facts in connexion with the war is that there is no sort of agreement as to the best method of treating septic wounds. Are we to use antiseptics at all? And if so, what antiseptic? An impartial observer might come to the conclusion that the best treatment depended on the locality. In France, he might say, wounds do best without any antiseptic at all; in England, especially in the Midlands, Dakin's antiseptic is the best; whereas when we cross the Tweed there is nothing to compare with eusol. The fact is, of course, that good results are obtained by all methods (why this is the case I shall discuss in a subsequent paper), and that the skill of the surgeon is of much greater importance than the particular form of lotion he happens to be enamoured of for the moment. I think we may lay down the general proposition that if a wound is properly cleansed and properly drained at a sufficiently early period, there ought to be *no* deaths from sepsis. I am speaking exclusively of wounds as I have seen them in France. But this does not absolve us from the duty of testing all methods of treatment which may be applied subsequently to this surgical toilet of the wound, for some may give us quicker and more painless results than others, and may be easier of application in unskilled hands—a point of considerable importance under conditions such as obtain at present. It behoves us, therefore, to study very carefully all the processes which go on in a wound, and, in particular, the effects of the substances which we propose to apply thereto; and to study them, not only in relation to their action on the bacteria in the wound, but also on the cells and juices of the body itself. The latter is a matter of great difficulty, and I defer its consideration for the present.

It would appear obvious that the first essential in the study of antiseptics for this purpose would be a determination of the relative (and, if possible, absolute) potencies of the various substances which are in use, and it is very surprising to find that this has not been done. Thus I find in a recent paper the carbolic coefficient of a certain antiseptic is solemnly quoted as affording evidence of its value in wounds! Applying this test, we should be led to the belief that perchloride of mercury would sterilise wounds or the secretions from them at a dilution of 1 in 15.000 or thereabouts, whereas it is actually efficacious in a dilution about 100 times less. The carbolic acid coefficient may have a commercial value, but it has no other. More recent writers have tested the action of their antiseptic on bacteria suspended in serum. This is much better, but it is still not good enough. I know of no condition which occurs in surgical practice in which the problem is to sterilise blood serum.

In the early stage of a wound it is filled with blood and blood-clot; in the later it is filled with pus. Obviously, therefore, we should test the action of antiseptics on these substances. Now pus is a very undesirable substance to test in this way for several reasons. In the first place, there is no uniformity in its composition, either as regards the substances in solution or as regards the number of cells. And, more important, the number and nature of the organisms vary enormously, so enormously as to deprive our results of any value whatever. For example, pus containing streptococci only may be completely sterilised when mixed with an equal volume of 1 in 60 carbolic for 15 minutes, whereas if the spores of B. perfringens are present (as is usually the case) they are not necessarily killed when the pus is mixed with equal volumes of 1 in 20 carbolic and incubated at the body temperature for two days. I suggest, therefore, that unless we can find a method of preparing pus of standard composition, and containing a standard number of bacteria, we should abandon this method of testing antiseptics.

Blood presents no such difficulties. It is always at hand and always reasonably constant in composition, and we can add to it what bacteria we like and in the proportions we like. Moreover, it is the actual substance that we have to

deal with if we attempt to sterilise a wound in the earlier stages. Blood therefore appears ideal for the purpose.

In actual practice we have to prepare the blood so that it does not clot. We may use citrated blood, using the smallest amount of citrate possible so as to avoid excessive dilution, but this method fails us if we have to deal with antiseptics containing calcium salts, for these will bring about coagulation in our citrated blood. A better method, though one that is a little more troublesome, is to use "reconstituted blood," made by adding equal amounts of serum and of washed corpuscles. It is prepared as follows. Collect some blood from the finger in a Wright's capsule and allow it to clot. Collect about the same amount of blood, allowing it to drop into citrated saline; centrifugalise; decant off the clear fluid; add normal saline, stir, and centrifugalise again; again pipette off the supernatant fluid and replace it by serum in amount equal to the deposit of corpuscles, and stir. This will give you a fluid almost identical with blood, except that it is uncoagulable.

As regards the organism to be added, for general purposes streptococcus fæcalis (or the enterococcus) is all that can be desired. It is our chief enemy in wounds; it can always be obtained without any difficulty in pure culture; it grows rapidly, so that the results of tests made in the morning can be read off in the evening; and, as a small but important practical point, it readily emulsifies, so that there are no masses to resist the action of the antiseptic. Of course, for other purposes other cultures may be used. The inventor of a new antiseptic might prefer to use B. coli or B. typhosus, which are much more easily killed, whereas the opponents of all antiseptics might use the spores of B. subtilis, and find that it was almost impossible to kill them by any antiseptic; and justify his action by showing that they were very common early infections of wounds. But the streptococcus is sufficient for all ordinary purposes.

Next, as regards the number of these bacteria. This is a point of very considerable importance, and one that calls for some theoretical consideration. The death of a bacterial cell might be considered as being due to the combination of a certain number of molecules of the antiseptic with the protoplasm of the cell; and hence it might be argued that the amount of antiseptic required would be proportionate to the number of bacteria, supposing, of course, that they are suspended in an inert fluid. This is incorrect, for the reason that all bacteria in an apparently homogeneous culture are not alike. Some, perhaps, have just divided, and have not formed a protective cell-wall; others, *pace* Weismann, are decrepit from old age; whilst still others are as strong and resistant as it is possible for a bacterium to be. Hence, if we test our antiseptics on a small amount of culture we shall get varying results according to the condition of the microbes that we happen to take. We can overcome the difficulty in two ways, by using large volumes of the mixture to be tested or by making a relatively heavy inoculation of the blood we are going to use as our test fluid. This is the more convenient method, and in order to take a definite figure I have used throughout a mixture of 9 parts of blood and 1 part of an 18-hour culture of streptococcus, containing about 250,000,000 cocci per c.c. It would perhaps be a little more accurate to count the culture before use, and to add a definite number, but if the same culture is inoculated in the same way into the same amount of standard broth the results are very constant, and with the large implantation given small variations are not of much effect. This is one of the advantages of a heavy implantation, such as I recommend.

The next question concerns the time during which the antiseptic should be allowed to act. This brings us to a point of the greatest importance, but one, I think, that has hardly been adequately dealt with. All antiseptics combine with proteins in solution, or with cells, and hence bacteria lying in pus or blood are shielded from their action. This is recognised as the "quenching" action of these fluids, and it is well recognised that the effect is much greater with different antiseptics; mercury salts, for example, are quenched to an enormous extent, carbolic acid relatively but little. But this is not the whole story. The mixtures of some antiseptics and blood will become an unfavourable culture medium for bacteria, or the compound of the antiseptic and the protein will dissociate, giving a slow but continuous antiseptic action, such as is desired by some surgeons, and referred to as a "depôt-action." With other antiseptics this is not the case, and the antiseptic is either completely destroyed or, at least, rendered inert by combination with protein. Hence if we test the former on infected blood, making a mixture that is not completely sterilised in a certain period of time, say 15 minutes, and then re-test from time to time, we shall find the number of bacteria will steadily fall off. With the second group, on the other hand, there will be a transitory fall in the number of bacteria, after which they will grow, perhaps not so well as before, but under some conditions much better. Carbolic acid is an example of the first class, eusol of the second. For example, a mixture of carbolic acid and infected blood which is just not sterilised in a quarter of an hour will be completely so in one hour, whereas a mixture of eusol (undiluted) and infected blood in equal parts will show some diminution in the number of bacteria if tested after a quarter of an hour, whereas if it is re-tested after one hour abundant growth will have taken place, and it will be indistinguishable from the control. I know this will appear a hard saying to many, but I have no doubt as to its correctness; the addition of eusol in amount insufficient to cause complete destruction of the microbes has no appreciable deleterious effect on the fluid as a culture medium for what remain. I advise, therefore, that the effect of the antiseptic shall be tested after two periods of exposure, and for all practicable purposes these may be 15 minutes and 60 minutes. It might be a good plan to add a third, 2 hours.

As regards the temperature of exposure there can be no difference of opinion. The mixture of antiseptic and infected blood must be incubated at the temperature of the body, the temperature at which they are to be used in practice.

Lastly, what criterion of killing are we to adopt? There is a general idea that the planting-out subsequently to the exposure to the antiseptic must be done in a large quantity of broth, so that any antiseptic may be diluted to such an extent that it ceases to act. I think this is a theoretical point only, and the method quite unnecessary in actual practice; and it has the great objection that it only tells us whether there is or is not complete sterilisation of our test-fluid. If, on the other hand, we plate out on agar and count the colonies that grow up we can tell what dilution of antiseptic will cause partial sterilisation, and what complete; and, moreover, it avoids the possible fallacy that a single microbe which had accidentally escaped contact with the antiseptic, might vitiate our results. The theoretical objection to this method does not take into consideration the fact that most—as far as I know, all—antiseptics diffuse well through agar, so that it is not correct to argue that when a mixture such as I have described is plated out the antiseptic continues to act on the microbes for an indefinite period; it diffuses rapidly away into the substance of the agar, the microbe remaining on the surface. As a matter of fact I have made parallel observations with the two methods, and have got in most cases absolutely identical results.

The technique I have used is quick and easy. The requisites are: (1) infected blood, prepared as described above; (2) the antiseptic to be tested, in suitable dilutions; (3) a stock of capillary pipettes, such as are used in the opsonin technique; (4) large agar-plates, deep, so as to allow diffusion of the antiseptic, and surface dry; (5) a standard platinum loop about 2 millimetres in diameter; and (6) some slides which, when sterilised by flaming, are used to prepare our mixtures on.

The process is as follows. Fit an indiarubber teat to one of the pipettes, and make a grease-pencil mark on the latter about 2 inches from the tip. Then take one volume of infected blood and one volume of antiseptic and mix thoroughly on the sterile slide. Suck back about half into the pipette and seal. Take the other half into another pipette and seal it also. Place the two pipettes in the incubator, noting the time (an opsonin incubator is a great advantage). Repeat the process with the other dilutions of antiseptic, making in each case a mixture of equal parts of antiseptic and infected blood. At the end of a quarter of an hour remove the first of your dilutions, fit on an indiarubber teat, and cut off the tip of the pipette. Sterilise the end lightly in the flame, and expel the contents of the pipette on to a sterile slide, and mix thoroughly. Now take a loopful, avoiding bubbles, with the platinum loop, and spread

it out over as large a surface as possible on the agar plate. Repeat this with the other dilutions when their 15 minutes' incubation is up, and with the second series after an hour has elapsed. Incubate the plates; growth is complete in 24 hours, but the results can be read off before then.

I append some of my results:—

Antiseptic.	15 minutes.		60 minutes.	
	Does not kill—	Kills—	Does not kill—	Kills—
Carbolic acid	1 in 70	1 in 60	1 in 60	1 in 50
Eusol...	Undiluted.	—	Undiluted.	—
Dakin	,,	—	,,	—
Perchloride	1 in 100	1 in 80	1 in 100	1 in 80
Biniodide...	1 in 60	1 in 40	1 in 60	1 in 40
Iodine	1 in 100	?	1 in 100	?
Lysol...	1 in 40	1 in 30	1 in 150	1 in 120
Malachite green ...	1 in 250	1 in 200	1 in 250	1 in 200

The expression "does not kill" may be taken in most cases as implying that it causes a diminution in the number of organisms, but does not effect actual sterilisation; this dilution, therefore, may be taken as a convenient end-point if various antiseptics have to be compared. For instance, there is a tradition that eusol and Dakin's solution are several times more powerful than carbolic acid, whereas, as a matter of fact, it is seen when this method of testing is used that these substances undiluted (0·5) are about equal in effect to a 1 in 70 dilution of carbolic—in other words, carbolic acid is 70 times as strong. But this is only if they are tested at the end of a quarter of an hour; if tested at the end of one hour the chlorine preparations appear to be quite inert, the surviving bacteria having grown until, unless special methods of plating are used, they appear as abundant as in the controls. To demonstrate complete killing with eusol it is necessary to have approximately two volumes of the antiseptic to one of blood.

The killing point of iodine is not given. It is about 1 in 60, but at a dilution like this the blood is turned into a thick pasty mass, very unsuited for accurate work. Iodine is sometimes used in a dilution of 1 in 300 or 400 to "sterilise" wounds. Such a dilution is quite inert.

The results with malachite green may excite surprise; it is by far the most powerful antiseptic that I have investigated. Unfortunately its action on the living cells is even more powerful, otherwise it would be the ideal antiseptic for surgical use.

This work was carried out for the Medical Research Committee, to whom my best thanks are due.

Harley-street, W.

THE TREATMENT OF HÆMORRHOIDS BY INJECTION.

BY F. SWINFORD EDWARDS, F.R.C.S. ENG.,

PRESIDENT OF THE SUB-SECTION OF PROCTOLOGY, ROYAL SOCIETY OF MEDICINE; CONSULTING SURGEON TO ST. MARK'S HOSPITAL FOR DISEASES OF THE RECTUM AND WEST LONDON HOSPITAL; AND SENIOR SURGEON TO ST. PETER'S HOSPITAL FOR URINARY DISEASES, ETC.

As mentioned by Mr. Arthur S. Morley in an excellent paper under this heading which appeared in THE LANCET of March 18th, I brought this subject before the profession in a paper published in the year 1888.[1] I was led to try this method as a substitute for operation by reports from certain American surgeons, amongst whom was Van Buren, professor of surgery in the Bellevue Hospital. In his work on "Diseases of the Rectum" in 1881 he makes mention of the injection of carbolic acid, and states that Professor Andrews, of St. Louis, had collected some thousands of cases treated by carbolic acid, and his conclusions, although in a general sense favourable, are not such as to tempt us to abandon safe and well-known methods without still further trial He says: "Most of the cases thus operated on suffer a sharp temporary smarting, and a few have a terrible and prolonged agony. The majority, however, are cured without interrupting the patient's business."

[1] Brit. Med. Jour., Oct. 13th, 1888.

In spite of this somewhat unfavourable verdict I determined to try this method amongst the out-patients at St. Mark's Hospital. After an experience there of a hundred cases I came to the conclusion that with proper precautions it was quite safe, and except in one or two cases absolutely free from pain. One injection sufficed to cure some, but the majority required two or three spread over some months. It failed in one or two cases owing to prolapse of the swollen piles on the patient's way home, followed by strangulation and sloughing. This was the result of neglect in obeying the instructions given—namely, to replace the piles at once should protrusion occur. These patients were afterwards admitted and underwent the usual operation of ligature by Salmon's method.

The injection treatment having proved so satisfactory, even amongst the out-patients of a hospital which, on account of the long way many had to go in returning to their homes and to a lack of intelligence in some, is a severe test; I adopted it in private, and have continued its practice ever since with satisfaction to my patients and without an accident of any kind.

Mr. Morley uses, I see, the same injection as I do and of the same strength—viz., 20 per cent. of carbolic acid in equal parts of glycerine and water. At first I worked with a 10 per cent. solution, but found on increasing the strength that recurrences were less frequent nor was it attended with pain. I am in thorough accord with all Mr. Morley says as to the cases amenable to this treatment, the precautions necessary for a successful issue, also as to the wonderful saving of time, expense, and sometimes of pain achieved by its adoption, but my technique somewhat varies from his. It is as follows. The piles having been protruded, possibly with the aid of an enema, the patient is placed in the knee-elbow position with the buttocks opposite a good light. The parts are then sponged over with some antiseptic, as lysol and water, and the injection made through a sterilised needle. From 3 to 6 minims of the carbolic solution is injected into the centre of each pile in turn. In large piles I often inject 5 minims in two places. The piles are then smeared with vaseline or sulphate of iron ointment, and returned as soon as possible, for the injection always causes the hæmorrhoids to swell, therefore the longer they remain outside the more difficult are they to return. I advise no action of the bowels for 48 hours, and should prolapse occur in the meantime immediate replacement is essential.

Whilst he injects the piles *in situ* through an anal speculum I always get them prolapsed first and inject them whilst still protruded, returning them immediately afterwards. I am glad to hear that he injects all the piles at one sitting, for this is what I have always done. Several writers have advocated only injecting one pile at a sitting, but I cannot see any reason in this, an unnecessary loss of time it seems to me.

My reasons for having the piles extruded before injecting them are these: 1. It is much easier and one is more certain of getting into the centre of each pile. 2. If the piles are injected through a speculum a special long syringe, such as described by Mr. Morley, is necessary, whereas an ordinary hypodermic syringe suffices when the piles are prolapsed. 3. Piles which cannot be protruded should be left alone. They are to be cured by palliative means, such as local applications, enemata, attention to diet, and regulation of the bowels, &c. 4. An assistant is almost a necessity if a speculum is used, and should any bleeding occur on the withdrawal of the needle, is indispensable. I do not suppose this is as likely to take place as when the piles are prolapsed, but it might occur, when an extra pair of hands would be useful.

As I have said, a large number of cases of internal hæmorrhoids can be cured by palliative treatment—by this I do not mean the use of nutgall ointment,—but when protrusion occurs on exertion or at stool, when bleeding is sufficient to cause anæmia and troubles arising therefrom, or when the piles protrude and require replacement, some operative interference is imperative. Before any operation is undertaken it is essential that a thorough examination should be made to avoid overlooking a rectal carcinoma or other trouble high up, an accident which even to-day is constantly happening in spite of repeated warnings from others (Mr. Morley included) as well as myself. Cases fitted for injection are those of uncomplicated internal hæmorrhoids which can be protruded, then returned and kept

within the bowel. In hospital practice one finds really but few cases of uncomplicated piles, for most of those admitted for operation have in addition one or more of the following lesions—viz., external tags, fissure, hypertrophied papillæ, ulceration, and even fistula, or are of the intero-external variety. In a short paper [2] on this subject, to show how comparatively few cases are fitted for the injection treatment, I instanced an afternoon's work at St. Mark's Hospital, where I had 11 cases of piles to operate upon. Of these, 10 were complicated by other lesions—viz., 4 with fissure, 4 with external piles, 1 with an anal ulcer, and 1 with a thrombosed internal pile. In private, however, the reverse is usually the case.

I am in accord with Sir James Goodhart and one or two other writers that this method of treatment deserves to be more generally employed than it is at present, but he seems to have arrived at this conclusion from a somewhat unfortunate experience of the immediate and after-results of operation, whether by the ligature or by Whitehead's method.[3] His experience of the latter coincides with my own. Theoretically it is splendid, but practically it is far inferior to either the ligature operation or to the clamp and cautery, so that I never advise this method and I am glad to see it is rapidly falling into disrepute. But concerning the former, after an experience of over 6000 operations for hæmorrhoids, I may say that I think there is no more successful operation in the whole range of surgery than is "Salmon's" ligature operation as practised to-day. It is equally fitted to both simple and complicated cases, is devoid of risk, often but little pain is complained of, and convalescence is usually a matter of three weeks. If properly performed recurrence is so rare that it need not be taken into account. It is quite true that an anal stricture may result, but if this necessitates an operation it is generally owing to neglect or ignorance on the part of the medical attendant. If a finger is passed between the eighth and tenth days—i.e., when the ligatures have separated—any suspicion of on-coming contraction is discovered and dilatation at once regularly resorted to. In such cases at all events we can promise no further return of piles. Although I have often had to dilate about a fortnight after the operation either with a bi-valved speculum or with metal dilators, I have never had to resort to a cutting operation to cure this condition.

After the injection a few hours in bed are advisable, after which the patient can walk about and attend to his usual occupation. He has no pain and begins to get better at once. Often all bleeding and prolapse cease after the first injection, which may suffice for a cure. Latterly I have not often had to repeat the injection, and when it is necessary a year has probably elapsed and all the symptoms are ameliorated.

The great advantages of the injection treatment are: (1) No confinement to bed excepting for a few hours when possible: (2) no anæsthetic, and therefore no post-anæsthetic vomiting; (3) no pain; (4) no enforced absence from business; (5) no risk from the little operation itself and no risk of stricture or incontinence following; and (6) immediate and steadily increasing betterment.

As an advocate for this method, I cannot put it stronger than by saying that if I were the subject of uncomplicated reducible internal hæmorrhoids which called for operative interference I would select injection in preference to any of the recognised operations, always provided that it could be carried out by one who had had at least *some* experience of its simple technique.

Grosvenor-street, W.

[2] Practitioner, March, 1915.
[3] Ibid., December, 1914.

NORFOLK AND NORWICH HOSPITAL.—The report of this institution for the year 1915 shows that 2281 patients from the British Expeditionary forces were admitted to the wards, making a total of 3218 wounded who have received treatment since the commencement of the war. The death-rate for the year was only 0·8 per cent. In addition 295 men from the troops in training in the district were treated, the death-rate in this case being 2 per cent. The total number of in-patients, civilian and military, treated during the year was 5057, while the out-patients numbered 5492. The income for the year was £29,853, and the expenditure £26,437, the deficit on the accounts thus being reduced from £4073 to £823.

METHODS OF PREPARING SPHAGNUM MOSS AS A SURGICAL DRESSING.

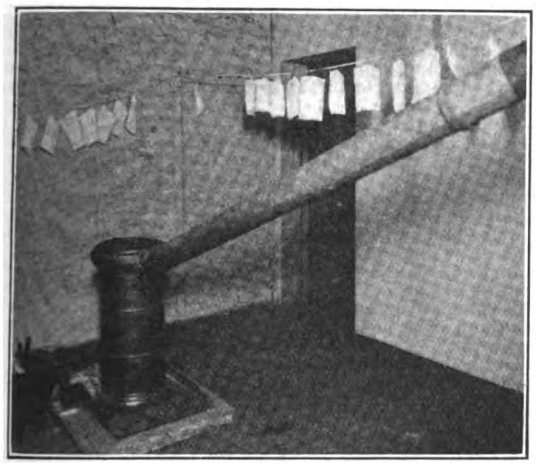
BY CHARLES W. CATHCART, F.R.C.S.,
SENIOR SURGEON, ROYAL INFIRMARY, EDINBURGH; LIEUTENANT-COLONEL, R.A.M.C. (T.)

THE War Dressings Supply Organisation, Edinburgh, has latterly dealt with sphagnum moss exclusively, while in many parts of the country the voluntary organisations for preparing hospital requirements have added new departments for dealing specially with it. Miss McCaul, the organiser of the admirable St. Marylebone War Hospital Supply Depôt at 2, Cavendish-square, London, was the first to take it up in England, and others have followed her example. In the near future the enterprise is likely to develop rapidly.

In the present paper I wish to draw attention (1) to the relative merits and advantages of three useful methods of preparing the moss—namely, sterilising by steam, "sublimating," and compressing; and (2) to the feasibility of carrying out these methods, including compression to a limited degree, by the use of simple appliances, and in premises easily obtained. These special methods begin after the moss has been collected, picked free of grass, leaves, sticks, &c., and dried. This work should, if possible, be carried out before it is sent to the central workrooms. In its natural state the moss contains a few non-pathogenic organisms, mostly moulds, but as other germs may obtain access to it sterilisation is necessary. Two methods have been employed:—

1. *Sterilisation by steam.*—This method, whether carried out in a high- or a low-pressure steriliser, hardens the walls of the minute tubules, and inhibits, although it does not destroy, the absorbing power. When fluid reaches the moss—especially warm fluid—the tubes are again softened and absorption takes place, although somewhat slowly. Sterilised pads of sphagnum moss, even when applied dry, have proved to be a better absorbent dressing than cotton-wool. Testimony to this effect has been received from war hospitals in all parts of the continent and Great Britain. If such pads are, however, wrung out of an antiseptic lotion just before use the full power of absorption is restored, and this simple procedure is to be recommended.

2. *Sterilisation by corrosive sublimate.*—This has been chosen as a suitable antiseptic material with which to charge the moss. It is non-volatile, relatively cheap, and very powerful. Moreover, the sublimating process is easily carried out and does not at all affect absorptive power. Contrary to what might have been expected, corrosive sublimate does not become fixed, and is readily given out again so as to render antiseptic any fluid which the moss absorbs.



Apparatus required for sterilising by steam.—This method may be employed before the dressings are sent to the hospitals, in which case it will be better to obtain the use of a steam disinfector, which is a steriliser on a large scale; or it may be employed at the hospitals, when the hospital or operating theatre steriliser can be used. For the use of small hospitals and for army purposes near the front I have described [1] a simple portable low-pressure steriliser which has done good service in war hospitals at home and abroad. As some surgeons doubted the effectiveness of steam at atmospheric pressure for surgical dressings, I have had this steriliser re-tested recently. Professor James Ritchie, who kindly undertook the tests, found the results perfectly satisfactory. Copies of his report can be obtained from the makers, Messrs. J. H. Thom and Co., 67, Dundee-street, Edinburgh. The original maker has been appointed to the charge of a large factory in South Africa.

Protection of dressings after sterilisation.—This can be done in one or other of several ways:—

1. To enclose them in material permeable to steam but proof against the entrance of solid particles. This is the method adopted by the Edinburgh War Dressings Supply Organisation. Groups of moss dressings are sewn up in flannelette bags, which after sterilisation are not opened till they reach the hospital where they are to be used. The flannelette can be used by the nurses as lint or in many other ways.

[1] Brit. Med. Jour., Dec. 19th, 1914.

FIG. 1.

Drying room: the slow-combustion stove.

2. To enclose them in boxes or wrappings of close paper or waterproof cloth, impermeable both to steam and to dust, but left open at one or two places during exposure to the steam. By the great penetrating power of saturated steam—a power quite independent of its pressure—the dressings are thus efficiently sterilised. The apertures in the coverings having been closed with due precautions, the dressings are afterwards quite safe. This method, with various individual modifications, has been adopted by several other organisations.

Sublimating the moss.—The object is to charge the material with a given percentage of corrosive sublimate.

The proportion adopted for moss is that commonly added to cotton-wool—namely, 0·25 per cent.; thus 100 lb. of sublimated moss or cotton-wool would contain ¼ lb. of corrosive sublimate. Reckoning the lb. avoirdupois as 7000 grains this would give 17·5 grains of sublimate in every pound of moss. A very convenient way of obtaining these 17·5 grains is to use two of the tablets issued commercially for making a 1 in 1000 sublimate lotion in 20 oz. of water. Each tablet contains 8·75 grains of sublimate.

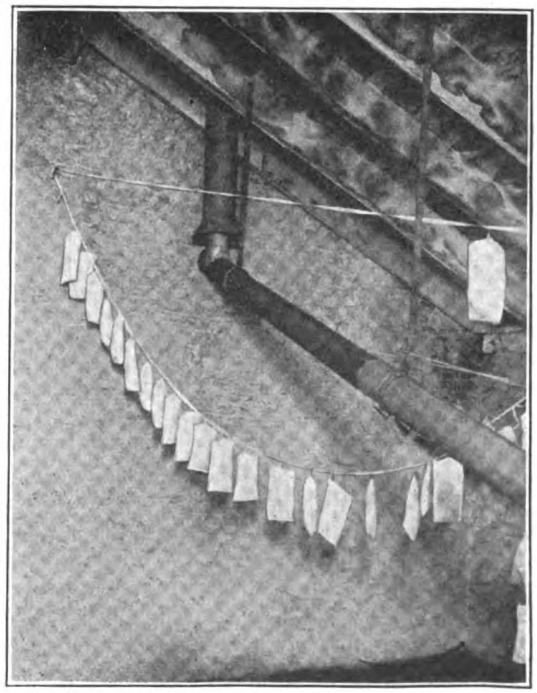
In order to determine the strength of the solution in which to soak the moss we must find out what will be a convenient quantity of fluid to leave in the moss after it has been wrung out of the charging solution. This will depend, among other things, on the efficiency of the squeezing apparatus. The exact quantity does not matter so long as the method adopted in making the calculation is always adhered to afterwards. When using the appliance described below it will be found quite easy by suitably adjusting the tightening screw to leave 20 oz. of water in every pound of moss. Thus, 16 oz. of dry moss will weigh 36 oz. after having been soaked and wrung. A few experiments with water should be tried in order to find how many threads of the screw have to be brought into action in order to produce this result. When this degree of compression has been attained this will be the tension required afterwards. Any number of gallons of solution can be made by adding at the rate of two tablets to each imperial pint of water. This, a 1 in 500 solution, is a very powerful antiseptic.

With regard to premises and apparatus, I have, after consultation with an architect friend, Mr. Jerdan, transformed an empty hay-loft with a wooden floor into a sublimating and a drying-room, and have equipped it with the necessary appliances of a simple character so as to make sure that such a scheme is feasible at a small cost. The methods employed can be carried out in country districts with the help of a village carpenter. Modifications of such an arrangement could be easily made if the principles involved in this example are understood.

The drying room may be described first, since this involves structural alteration. We need a chamber the air of which can be heated to 70° or 80° F., while the air is being constantly renewed so that the accumulating vapour may be carried off.

As the heating arrangements bear a proportion to the cubic space to be heated, it may sometimes be necessary, as in my case, to run a partition across a room which is bigger than required. It occurred to me that a very simple form of partition would serve if it were composed of two air-proof surfaces with a good layer of air, as a non-conducting medium, between them. This has proved quite satisfactory. An open frame-work of wood was erected from floor to ceiling at the desired distance from one end of the large room. The light standards employed were 6 inches broad to ensure sufficient air space. The coarse canvas known by builders as "scrim" was then stretched over each side of the frame-work and nailed to the wood, and white wall-paper was pasted over the canvas. The position of the doorway through the partition was chosen so as to be close to the spot where the stove was to stand for a reason explained later.

The heating arrangements were carried out so as to utilise all the heat available from a slow-combustion stove while ensuring a constant exchange of air. At one corner of the room, now shut off by the partition, an open form of stove had been previously fixed up with a large flue running vertically upwards inside the room to the roof. This stove was removed and the flue cut off a few feet from the roof. (I had wanted it cut at a higher level, but the present arrangement—finished before I saw it—seems to work quite well.)



A slow-combustion stove[2] was placed on a paving stone near the door (Fig. 1) at the opposite end of the room from the site of previous stove, and the flue from the new stove, 4½ inches in diameter, was carried obliquely upwards, suspended from the roof, until it passed inside the cut end of the original flue 6¼ inches in diameter. (Fig. 2.) The space thus left between the two flues serves a double purpose—viz., it obviates risk of fire at the roof and it causes a steady up-draught of vapour-laden air during the drying process.

The entrance for cold air is provided in the lower panels of the door, where a number of inch holes bored through the wood are protected with adjustable shutters. The windows are covered over with translucent tracing cloth at a little distance from the glass to establish an air-space, and as all other apertures in the room are closed the cold fresh air has only a few feet to traverse before it reaches the stove. Having been thus heated low down at one end of the room it rises and circulates until it escapes near the ceiling at the other end. The hot flue, as it passes through the room, of course greatly supplements the heating action of the stove. The floor of the drying-room measures 14 ft. 6 in. by 12 ft. The partition is 10½ ft. high and 14 ft. 6 in. long, except where the door passes through it. The ceiling extends at the full height of the partition for 4 ft., after that it slopes down to a height of 6 ft. at the outside wall of the building.

When the drying room was tested the air in the outer or sublimating room was about 47° F., as shown by a thermometer hung against an outer wall—i.e., much the same as the temperature of the outer air on that day. A thermometer hung against the partition stood at 50°. In the drying

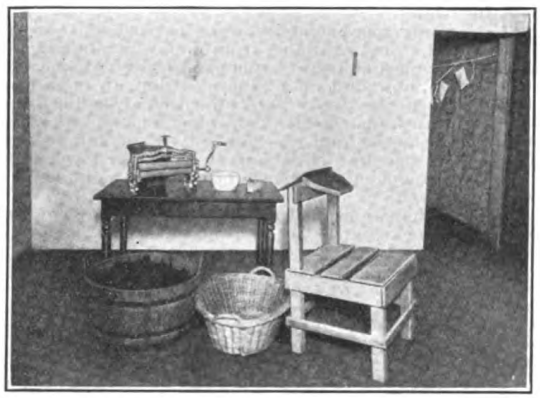

FIG. 2.

Drying room bags hanging on lines.

room a thermometer on the partition back to back with the one in the sublimating room registered 76°, and in a warmer, but not the warmest, part of the room a fourth thermometer stood at 79°. A series of sublimated bags were dried in 12 hours. Considering that sphagnum moss is very difficult to dry, and that the stove was not being burned at all fast, these results are quite satisfactory.

FIG. 3.

Sublimating room: the apparatus required.

Sublimating room.—This room need not be larger than suffices for the convenient working of the sublimating appliances. It should be as near as possible to the drying room, if not actually next to it. The sublimating process involves making the solution, soaking the moss in it and wringing the moss partially dry again. (Figs. 3 and 4.)

To make the solution we require a supply of the tablets of corrosive sublimate (to be had through a chemist); an enamelled or earthenware bowl and a pestle, or a piece of hard wood, for breaking them down quickly, a pail, and a pint measure for measuring out the required quantity of water.

The moss must be soaked in a wooden, enamelled, or earthenware tub, as corrosive sublimate will attack any exposed metal. For the same reason the solution should not be allowed to pass down metal drain pipes; this restriction will cause no inconvenience, since the solution squeezed out of a given quantity of moss can be used over and over again. A large oak washing-tub, 26 inches in diameter and costing 9*s.* or 10*s.*, makes as good a soaking tub as one could wish. It should stand on a "tub-chair" or "tub-stool" such as is used by cottagers; they are to be had ready made. On the upright rail or back of the tub-chair the wringer is attached, and to facilitate the work of "sublimating," the following simple woodwork should be fitted under the wringer by a carpenter. On the tub side of the wringer one shelf should slope down from the rail towards the tub. It should have a fillet of wood on each side so as to make a channel which narrows from the full width of the rollers as it passes backwards. This channel leads the solution squeezed out back into the tub. On the other side of the rail a second shelf sloping away from the tub directs the moss bags as they leave the wringer into a clothes-basket placed below. Between the two shelves a short vertical partition should rise up to prevent the solution, carried forward by the lower roller, from reaching the front shelf and wetting the moss again. Its upper edge should be about ½ inch below the line of junction between the two rollers and about ¼ inch from the surface of the lower one—not closer. The wringer I have used is known as the "Acme," costing about 24*s.* It has rubber-covered rollers, 16 inches broad. Other patterns would, no doubt, serve the purpose equally well.

For the purposes of a simple outfit there are several advantages in sublimating the moss in muslin bags rather than in loose form, which is only required when the moss is to be compressed into plates by hydraulic pressure. A medium-sized bag, about 7 × 4 inches, will be found very suitable. In the bag form the moss is very easily handled when being soaked, wrung, and dried; it is not exposed outside its bag after having been sublimated, and there are no loose fragments of moss to make a dust or catch fire in the drying room. In addition, by the use of the wringer the dried bags can be compressed to a degree which is of great practical use for packing purposes, although not so complete as that produced by expensive hydraulic machinery.

The actual work of sublimating can be done well by one person, but better by two. The bags are thoroughly soaked in the solution for a few minutes, then gently squeezed with the hands and passed through the wringer. Rubber gloves are necessary to protect the hands, as the sublimate hardens and cracks them.

A convenient and cheap way of hanging up the damp dressings in the drying room is to have a series of lines or ordinary tape hung up in suitable places. A common safety-pin is inserted first through the tape and then through the edge or corner of a bag. This is repeated at intervals of 6–8 inches until the line is full. (Figs. 1 and 2.) A good test of a bag being dry is that it crackles when gently pressed. Unless the bags were fixed to the line they would sag together at the centre, whereas for rapid drying each should hang clear of the other. When a bag is taken down the safety-pin remains to do duty for the next one.

Compression with wringer.—This method may be employed when it is important to reduce the bulk of the dressings for transport. The bags must be thoroughly dry in order to be compressed; a damp bag is elastic and springs out again. The rollers if damp must be dried with a clean towel. The maximum pressure having been produced by the tightening screw of the wringer each bag is passed through twice, once in its ordinary shape, a second time when folded once upon itself. This makes it into a firm easily handled piece less than half its original bulk.

The bags after having been sublimated and dried are ready for use whether in the compressed or the loose form. They must on no account be sterilised by steam. When being packed for transit they may be enclosed in either flannelette bags which have been separately sublimated or sterilised, in paper bags, preferably waterproof, or in waterproof cloth. All moss dressings being very absorbent should be protected from moisture, but this is specially true of compressed moss, which if wet would probably burst open the packing cases.

FIG. 4.

At work in the sublimating room.

The structural alterations were carried out by Messrs. John Watherston and Sons, builders, Edinburgh, at a cost of £10, exclusive of the disused stove, which, with its iron tray, originally cost about £2. The "tub-chair," costing about 7*s.*, was procured for me and altered to my design by Mr. Mitchell, 8, Lady Lawson-street, Edinburgh. Mr. A. H. Baird's photographic assistant, Mr. McConnachie, took the excellent flash-lamp photographs with which the paper is illustrated. No attempt has been made in this paper to describe the appliances kindly put at the disposal of the Edinburgh War Dressings Supply Organisation by Sir John Cowan at Messrs. Redpath, Brown, and Co.'s workshops at Albion-road, Edinburgh. The processes are exactly similar in principle but conducted on a much larger scale by the use of expensive machinery requiring steam and electricity. Sir John Cowan has kindly invited anyone practically interested in the subject to visit the works and inspect all that is being done.

Edinburgh.

A NOTE ON THE PRECIPITIN REACTION IN TUBERCULOUS FLUIDS.

BY S. ROODHOUSE GLOYNE, M.D. LEEDS, D.P.H.,
PATHOLOGIST, CITY OF LONDON HOSPITAL FOR DISEASES OF THE CHEST, VICTORIA PARK, E.

SINCE Kraus [1] first noted that precipitation took place when the blood sera of animals immunised against cholera were added to the filtrate of cholera cultures a new chapter of immunity has been written. Until quite recently, however, precipitins have received attention chiefly from the standpoint of the biologist and the medical jurist (Nuttall,[2] Graham Smith and Sanger [3]). The work of Ascoli [4] on precipitins in anthrax, Isabolinsky and Patzewitsch [5] in the typhoid-coli group, Iwicki [6] in swine fever, Piras [7] in bubonic plague, and Faginoli [8] in tuberculous sputum has suggested to the writer that this precipitin or bacterio-precipitin reaction might be of some use in the diagnosis of tuberculous pleural fluids in which bacilli often cannot be found without great difficulty.

Method.

Various dilutions of the fluid were made in test-tubes—viz., 1 in 5, 1 in 10, 1 in 25, and 1 in 50. A row of small test-tubes (3 inches × ¼ inch), each containing 0·5 c.c. of Koch's old tuberculin, was placed in a rack. To the first of these was added 0·5 c.c. of undiluted fluid, care being taken to pour it down the side of the tube, as in doing the nitric acid test with urine (a graduated pipette is almost essential for this). To the second tube was added 0·5 c.c. of a 1 in 5 dilution of the pleural fluid, to the third a similar amount of 1 in 10 dilution, and so on. Controls were also made with (1) 0·5 c.c. saline + 0·5 c.c. tuberculin, and (2) 0·5 c.c. saline + 0·5 c.c. undiluted pleural fluid. The rack of tubes was placed in the incubator for one hour and at the end of this time a positive result was indicated by the presence of a white ring at the junction of the two fluids. Usually this precipitation took place in all dilutions tested—i.e., up to 1 in 50—though occasionally it was absent in this last dilution.

Results.

Four definitely tuberculous fluids were tested (three contained bacilli, and the fourth, though no bacilli were found, was verified post mortem). Of these four fluids three gave positive reactions (75 per cent.). Fourteen fluids were also tested in which the diagnosis could not be definitely proved by the finding of bacilli, but in which a lymphocyte count, high protein content, &c., strongly suggested a tuberculous origin. Of these, five (36 per cent.) gave a positive reaction, two (14 per cent.) a doubtful, and seven (50 per cent.) a negative result. Four non-tuberculous fluids used as controls were all negative.

Conclusions.

It would be extremely unwise to draw any very definite conclusions from the few results here recorded, but it seems possible that the test may be of some use in cases of tuberculous effusion where bacilli have not been found in the fluid. It is also probable that the results might be improved greatly with more careful technique and a more delicate antigen. If it should prove reliable, the test has at least the advantage of simplicity.

ASYLUM WORKERS' ASSOCIATION.—The annual general meeting of this association will be held at 11, Chandos-street, Cavendish-square, W., on Wednesday, May 17th. The chair will be taken at 3 P.M. by Sir John Jardine, Bart., M.P., president of the association. The annual report will be submitted, officers elected, and presentations will be made of medals for long and meritorious nursing service. Matters of much importance to asylum workers will be discussed, and it is hoped that there will be a large and representative gathering of members and friends of the association.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

IMPERFORATE HYMEN IN A BABY:

A NOTE FOR PRACTISERS OF MIDWIFERY.

BY HERBERT R. SPENCER, M.D., B.S. LOND., F.R.C.P. LOND.,
OBSTETRIC PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL, LONDON.

FOR many years I have been in the habit of examining in the course of the puerperium the vulva of the babies I have delivered, with the view of detecting abnormalities, especially of the hymen. For want of this simple examination imperforate hymen escapes notice till menstruation occurs, when the pain, distension, ill-health, and non-appearance of the menstrual discharge lead to a gynæcological examination and the condition is discovered. Unfortunately, sometimes the distension of the genital tract has involved the Fallopian tubes when the case is seen; the patient has been rendered sterile, and the risk of treatment is much increased. All the cases I have seen of this condition have recovered after evacuating the menstrual blood through an incision in the hymen; but one patient in whom hæmatosalpinx had already formed and who refused to have the tubes operated on had a severe attack of peritonitis after the evacuation of the blood from the vagina and uterus.

The object of this note is to urge practisers of midwifery to make a routine inspection of the vulva of female babies before the puerperal attendance ceases. If the hymen is found to be imperforate and bulged forwards by secretion, a snip with a pair of scissors will save the patient from a grave risk to her fertility, health, and even life. The point may be illustrated by the following case in which the malformation was discovered by an observant mother.

A baby girl 11 weeks old was brought to University College Hospital on Dec. 4th, 1915, on account of a swelling in the vulva which the mother had first noticed a fortnight previously. On inspection the labia were separated by a cystic swelling of the size of a small marble which became a little more prominent when the infant cried. It was obviously the imperforate hymen. (See illustration.) Its most prominent part was seized with mouse-tooth forceps and an elliptical piece was snipped out; about a drachm of mucus escaped from the vagina, and the hymen sank back to its normal position. A thin strand of oiled gauze was inserted into the hymeneal opening for a few days. A fortnight later the parts had a normal appearance. The mother was instructed to bring the baby to the clinic from time to time in order to make sure that the aperture did not close.

Case of imperforate hymen in a baby (natural size).

Harley-street, W.

A CASE OF IMPERFORATE HYMEN.

BY WILLIAM ROBERTSON, M.D. GLASG.

THE patient was a strong native, otherwise without defect, 17 years of age, and had had menstrual molimina for three years. These had been severe and characterised by abdominal pain and pain in the back, but without the escape externally of any blood. Lately micturition and defæcation had been painful and obstructed. Everywhere the abdomen was soft and painless to palpation and only slightly distended. Percussion was normal. There was no fever or loss of appetite. There was perfect cessation of pain between attacks. The genitals were normal but for the thick, bulging membrane completely closing the introitus vaginæ. The urethra and

anus were more or less everted and distorted. The bulging septum, 3 inches long and 1¾ inches broad, was evidently under strong pressure, and resembled generally protruding membranes. Examination per rectum discovered a great tumour obliterating the lumen of that tube.

After passing the catheter and drawing off several ounces of clear, normal urine, with a trocar and cannula the septum was perforated (not easily) and black tarry fluid was ejected a yard or two. In all about 20 ounces of this fluid was allowed to run off gently. The next day I withdrew some more. Then with a catheter in the bladder and observing the anus (for the parts were now much contracted) a free opening was made with scissors and finger in the septum, notching it all round. All the parts were normal but for the huge distension of the vagina. The operation of emptying this hæmatocolpos produced no discomfort at all, while defæcation and micturition became normal and discharge from the vagina abundant and odourless; no injection was used. One or two salt and citrate tabloids were left in the vagina.

No doubt the menstrual flow was inhibited in amount owing to the pressure experienced during the three or four years of the obstruction. Escape of blood through the fimbriæ had not taken place in this case. The tendency for the opening to close is great in these cases; every effort must therefore be used to maintain the ground gained by suitable measures.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF PSYCHIATRY.

The Psychology of Rumour.

A MEETING of this section was held on March 28th, Dr. F. W. MOTT, the President, being in the chair.

Dr. BERNARD HART read a paper entitled "The Psychology of Rumour." Rumour he defined provisionally as the transmission of a report through a succession of individuals, the product of the narratives of a series of witnesses. The reliability of a rumour depended on the accuracy with which such statements were transmitted, and ultimately upon the accuracy of the report furnished by the first member of the series, who was assumed to have seen or heard the occurrence itself. The report furnished by the actual witness of an event constituted "evidence" in the legal sense of the term, and it was clear that an investigation of its psychology must logically precede that of rumour. In former days the criterion of reliability was held to be the moral character of the witness. The question debated at that period was whether a witness was honest or dishonest, or whether he was trying to mislead with definite conscious ends in view. If such scrutiny resulted in the individual's favour all his evidence was accepted. Nowadays, however, the reliability of each individual statement was separately estimated, each possible influencing factor being taken cognisance of, including the unconscious action of political and other bias. Extensive experimental investigations into the psychology of evidence had been carried out, especially by Stern and his school. The method adopted generally consisted of submitting a predetermined experience to a number of subjects who were subsequently required to furnish a report of their experience. These reports were compared with the original experience, and the various results in that way were evaluated. Two methods of obtaining the report were employed, the narrative and the interrogatory (cross-examination). These experimental investigations completely upset the naïve views still held generally by the laity—namely, that evidence given with the best knowledge and interest was a correct reproduction of actuality; and, secondly, that evidence which was false must be due to either lying or culpable carelessness. Completely correct reports were not the rule but the exception. One investigator found in 240 reports only 2 per cent. of errorless narratives. The average reporter, when no suggestive or leading questions were employed, exhibited a coefficient of accuracy of only 75 per cent. Attestation was not found to be a guarantee of accuracy, for even in sworn testimony 10 per cent. of errors were found to be present. On increasing the time-interval between the event and the report it was found that though range and accuracy were both diminished the degree of assurance of the reporter showed a surprising constancy. Hence a person's degree of assurance and readiness to swear to the truth of his testimony depended on the character of the person rather than upon the quality of his memory. Evidence given by children should be accepted with the greatest caution, for the assurance of children was relatively high, while their capacity for reproducing what they had seen was very low. After a historical résumé of the work of previous investigators, Dr. Hart proceeded to analyse the psychological factors leading to the perversion of evidence, dividing the processes involved into perception, conservation, and reproduction, and especially dwelling upon the part played by "complexes" in the distortions affecting each of these processes. The facts of pathology were of great help, and a consideration of hallucinations, illusions, the paramnesias of alcoholics and paralytics, and particularly of the condition known as "pseudologia phantastica," showed precisely the same causes at work as in the perverted evidence of the normal man, but, of course, in a more exaggerated degree. The action of phantasy was of the greatest importance both in pathological conditions, such as hysteria, and in the production of certain rumours in normal men. Dr. Hart passed on to consider rumour as a social phenomenon and analysed its relation to the psychology of the crowd. The views of Le Bon, Conway, and Trotter were described and criticised. The peculiar susceptibility of the crowd to the action of "herd instinct" explained the ease with which non-rational opinions and beliefs were embraced by it, and hence its increased liability to the acceptance and propagation of rumours. During a great war herd instinct was stimulated to a maximum degree, and the prevalence and vitality of rumour were, for the same reason as in the case of the crowd, also greatly enhanced. Dr. Hart concluded by enumerating and classifying the various types of rumours, analysing the factors responsible for their origin, and illustrating his contentions by examples drawn from recent history.

The ensuing discussion was participated in by the PRESIDENT, Sir GEORGE SAVAGE, Mr. J. C. FLÜGEL, Professor H. W. CARR, Dr. W. H. B. STODDART, Dr. PERCY NUNN, Dr. ERNEST JONES, and Mr. J. HERBERT PARSONS.

Dr. HART briefly replied.

ÆSCULAPIAN SOCIETY.—A meeting of this society was held on March 17th at the Metropolitan Hospital, Dr. P. Hamill, the President, being in the chair.—Dr. Stansfeld read a paper in which he considered the following applications of transfusion: 1. Immediate supply of red blood corpuscles in various types of anæmia. 2. Hæmostatic action. 3. Stimulation of blood formation. 4. Influence upon certain toxæmic conditions, such as the toxæmias of pregnancy, urticarias and bullous skin eruptions, &c. These indications, except the first, were, he said, met by the administration of serum, and the serum employed need not necessarily or always be of human origin. But against animal serum, even if proved to be as efficient as human serum, there are the objections of serum disease and the rendering of the patient anaphylactic, so that subsequent repetition of treatment may be harmful and even dangerous. Serum he considered to have advantages over whole blood in that it can be safely kept and more easily administered, while the changes which occur during the process of clotting may be of importance, and possibly they are sometimes advantageous. But in the treatment of anæmias, at least, he held it most rational to administer whole blood intravenously. The donor must be carefully selected. Isohæmagglutinins and isohæmolysins should be absent from the blood of both donor and patient; separate tests should be carried out for each pair of individuals, as even blood relationship does not necessarily afford security. The method employed could be: (1) Direct, by anastomosis, with or without a cannula; (2) indirect: (*a*) by syringe, as used by Lindemann; (*b*) by syringe and two-way tap; (*c*) with paraffin-lined receiver; (*d*) with receiver and use of an anticoagulant, such as hirudin or sodium citrate. Dr. Stansfeld then demonstrated his own apparatus, and reported the results in some of the cases treated, with special reference to pernicious anæmia.

Reviews and Notices of Books.

The Positive Sciences of the Ancient Hindus.

By BRAJENDRANATH SEAL, M.A., Ph.D. London: Longmans, Green, and Co. 1915.

ONE of the most important signs of a great awakening in India at present is seen in the fact that some of her best sons who were hitherto content to learn from oriental scholars like Sir William Jones, Colebrook, Wilson, Max Müller, and others are now diligently searching their Sanskrit literature themselves, and by their original investigations are furnishing much material to widen the scope of comparative science and thought. Dr. Brajendranath Seal, an eminent student of the literature of the East and the West, has, in his recent volume, given an insight into the early scientific achievement of the Hindu mind. In dealing with the positive sciences of the Hindus the author has largely confined himself to the millennial period, 500 B.C.–500 A.D. In the wide range of their intellectual activities the ancient Hindus excelled chiefly in philosophy, mathematics, and medicine.

1. *Philosophy.*—The main bulk of the philosophical systems of the Hindus must have been thought out about the time of Buddha, if not earlier. It is wonderful that with such poor materials and crude instruments at their disposal they should have made so much progress and anticipated so many discoveries of the last few centuries. To give one or two instances. The atomic theory of Kanada, the theory of the propagation of sound, of ether (ákáśa) in space, the statement that light and heat are but different forms of the same substance excite our admiration even at this distant date. The evolution theory of Kapilla, the originator of the oldest philosophy in the world, is remarkable for its originality and its daring conception of the oneness of the universe and of life. The ancients said: "The original Energy is one and ubiquitous, and everything therefore exists in everything else. ..... Inorganic matter, vegetable organisms and animal organisms are essentially and ultimately one so far as Mass and Energy are concerned." At the present day we are struggling in our doubt as to whether the inorganic can ever pass into the organic world, or matter into life. The ancient Hindus more than 2500 years ago believed that matter has no separate existence, but is only a manifestation of spirit, and that life is immanent in all things—thus brushing aside modern classification as artificial.

2. *Mathematics.*—Professor Monier Williams submits that "to the Hindus is due the invention of algebra and geometry and their application to astronomy." The Vaiśesika theory of motion is the nearest approach to Newton's First Law of Motion. The Vyasa-Bhashya (fifth or sixth century A.D at latest) contains the theory of potentials in a nutshell—the finest example before Newton of the exercise of scientific imagination. Dr. Seal supports the claim of Bhaskara (1150 A.D.) to be regarded as the precursor of Newton in the discovery of the differential calculus as well as its application to astronomical problems and computations.

3. *Medicine and Chemistry.*—Susruta's (of pre-Christian era) description of making caustic alkalies from the ashes of plants is a proof of the high degree of perfection the Hindus attained in scientific pharmacy at an early age. They were the first nation to employ preparations of mercury internally. The processes of calcination and sublimation were discovered by them. In the preparation of mineral acids and metallic salts, in advancing the knowledge of chemical compounds and utilising them in the service of medicine, Indians like Nágarjuna and Patanjali anticipated Paracelsus and his followers by several centuries. In chemical industries must be mentioned the three Indian discoveries which enabled India to command for so many centuries the markets of the East and the West: (*a*) the preparation of fast dyes for textile fabrics; (*b*) the extraction of the principle of indigotin from the indigo plant; (*c*) the tempering of steel in a manner worthy of advanced metallurgy. The materia medica of the Hindus is very voluminous, and many of the Indian drugs are found in the writings of Hippocrates, Dioscorides, Aetius, and Arabian works, and through them were introduced into European medicine. Clear references to the circulation of the blood, the difference between arteries and veins occur as early as in the writings of Charaka and Susruta who, however, attribute to the liver the part played by the lungs in the purification of blood. Susruta believed that the blood derived its colouring matter from the spleen. The Hindus were the first among the ancients to practise the dissection of the human body for purposes of demonstration. They used various forms of surgical instruments made from the finest steel for which India was justly famous from remote times. They performed amputations, abdominal section, lithotomy and cranial surgery, and gave as anæsthetics medicated wine, the inhalations of fumes of burning hemp, and a drug called sammohini (producer of unconsciousness).

The more that Sanskrit works are examined by competent Indian scholars, the more it will be evident how thoroughly the Hindus cultivated medical and other sciences as early as 500 B.C., between which period and 500 A.D they seemed to have reached the high-water mark in their civilisation. The author does not claim that the present volume contains a complete account of the subject. But by his original research he has broken new ground, and has therefore made a valuable contribution to the study of the scientific achievement of the ancient Hindus.

A Handbook of Medical Diagnosis for the Use of Practitioners and Students.

By J. C. WILSON, A.M., M.D., Emeritus Professor of the Practice of Medicine and Clinical Medicine in the Jefferson Medical College, and Physician to its Hospital. Fourth edition, thoroughly revised. London and Philadelphia: J. B. Lippincott Company. Pp. 1441. Price 25*s*.

IN our review of the third edition of this work[1] we explained the nature and scope of the book and expressed the favourable opinion we had formed of it. The present edition has brought the subject matter fully up to date, and many necessary changes have been made. The consideration of the electrocardiograph has been transferred to its proper place among instruments of precision. The normal tracings are explained, and some of the characteristic tracings of morbid conditions are shown, such as those of extrasystoles and auricular fibrillation. The section of Diagnosis by the Röntgen Rays has been entirely rewritten by Professor W. F. Manges. Amongst the more important laboratory tests the following have been duly noted: the macroscopic agglutination test in enteric fever; the luetin test in the diagnosis of tertiary syphilis; the Abderhalden diagnosis of pregnancy; and the complement-fixation test in the diagnosis of gonorrhœa.

In the section on Diseases of the Ductless Glands the subject of dyspituitarism and Cushing's arrangement of its clinical types have been added, and attention is called to the importance of the polyglandular syndrome. Amongst other changes we may mention that the paragraphs relating to the etiology of acute poliomyelitis have been rewritten in accordance with the results of the experimental work of Flexner and his associates at the Rockefeller Institute. These observers maintain that the causative micro-organism consists of filterable globoid bodies, measuring from 0·15 to 0·3 μ in diameter, and arranged in pairs, chains, or masses. Inoculation into the brain or the sciatic nerve and peritoneal cavity of monkeys is followed after an incubation period of 48 hours to several weeks by the clinical symptoms and pathological effects characteristic of experimental poliomyelitis.

The book as a whole is essentially of a practical nature, it contains a vast amount of information concerning clinical work, and the manner in which it is arranged renders it especially suitable for purposes of reference.

[1] THE LANCET, March 30th, 1912, p. 877.

ROYAL VICTORIA HOSPITAL, BELFAST.—At the annual meeting in connexion with this hospital, held on March 31st, the President, Lady Pirrie, in the chair, it was reported that 3189 new intern patients were received into the wards during 1915, and 29,145 new extern cases were treated. Among the ward cases were a large number of soldiers and sailors from active service. The total revenue for the year was £18,302, against £17,522 in 1914, and the disbursements £20,459, against £18,168 in the previous year, the difference being £2291. Seven of the members of the staff are serving their country at the front, two (Mr. A. Fullerton and Professor Sinclair) with the temporary rank of colonel

A MONTHLY RECORD OF ATMOSPHERIC POLLUTION.

COMMITTEE FOR THE INVESTIGATION OF ATMOSPHERIC POLLUTION:

Summary of Reports for Month ending Oct. 31st, 1915.

Place.	Rainfall in millimetres.	Metric tons of deposit per square kilometre during month.								
		Insoluble matter.			Soluble matter.		Total solids.	Included in soluble matter.		
		Tar.	Carbonaceous other than tar.	Ash.	Loss on ignition.	Ash.		Sulphate as (SO_4).	Chlorine (Cl).	Ammonia (NH_3).

[1] Results unreliable; gauge tampered with. [2] No returns. [3] No returns.

"Tar" includes all matter insoluble in water but soluble in CS_2. "Carbonaceous" includes all combustible matter insoluble in water and in CS_2. "Insoluble ash" includes all earthy matter, fuel, ash, &c. One metric ton per sq. kilometre is equivalent to: (*a*) Approx. 9lb. per acre; (*b*) 2·56 English tons per sq. mile; (*c*) one gramme per sq. metre; (*d*) 1/1000 millimetre of rainfall.

The public health authorities concerned in the supervision of these examinations were as follows: Dr. J. Robertson, Medical Officer of Health of Birmingham; Dr. J. E. Gould, Medical Officer of Health of Bolton; Mr. H. Lloyd Parry, Town Clerk, Exeter; Mr. A. R. Tankard, Public Analyst, Kingston-upon-Hull; C. K. Millard, D.Sc., Leicester; Dr. E. W. Hope, Medical Officer of Health of Liverpool; The Director of THE LANCET Laboratory, Meteorological Office, London; Mr. J. Ollis, Chief Officer, Public Control Department, London County Council, London; Dr. W. J. Howarth, Medical Officer of Health of London; Mr. W. Osborne Thorpe, Engineer, Urban District Council, Malvern; Mr. J. Warrington, Secretary, Air Pollution Advisory Board, Manchester; Dr. H. Kerr, Medical Officer of Health of Newcastle-on-Tyne; Dr. J. B. Wilkinson, Medical Officer of Health of Oldham; Professor W. P. Wynne, The University, Sheffield; Dr. E. M. Smith, Medical Officer of Health of York; Mr. A. G. Dutch, Sanitary Inspector, Coatbridge; Mr. J. Devine, Sanitary Inspector, Greenock; Mr. Thomas Bishop, Sanitary Inspector, Leith; and Mr. W. W. Kelso, Sanitary Inspector, Paisley.

The analytical work involved in these returns was undertaken respectively by J. F. Liverseege, F.I.C., Birmingham; Harry Hurst, B.Sc., F.I.C., Bolton; F. Southerden, B.Sc., F.I.C., Exeter; A. R. Tankard, F.I.C., Kingston-upon-Hull; S. F. Burford, Leicester; W. H. Roberts, M.Sc., F.I.C., Liverpool; S. A. Vasey, F.I.C., Director, THE LANCET Laboratory (London Meteorological Office collections); J. H. Coste, F.I.C. (Embankment Gardens, Finsbury Park, Ravenscourt Park, Southwark Park, Wandsworth Common, Victoria Park collections), London; F. L. Teed, D.Sc., Golden-lane, London, E.C.; C. C. Duncan, F.I.C., Malvern; E. Knecht, Ph.D., M.Sc., Manchester collections; J. T. Dunn, D.Sc., Newcastle-on-Tyne; Samuel Urmson, Oldham; Professor W. P. Wynne, Sheffield collections; S. H. Davies, M.Sc., York; Messrs. R. R. Tatlock and Thomson, Coatbridge; J. W. Biggart, F.I.C., Greenock; A. Scott Dodd, B.Sc., F.I.C., Leith and Paisley.

ATMOSPHERIC POLLUTION IN SHEFFIELD.

WE have received a copy of a report to the Health Committee of the Sheffield city council on the results obtained by the chemical investigation of rain-water collected at various sites in the city area. It is signed by Professor W. Palmer Wynne of the University, and his notes on the general scheme are of interest. The returns occur with those from other places in the monthly reports on atmospheric pollution which, as they are issued, appear regularly in our columns. Professor Wynne points out that these analytical data, in so far as they bear on the problem of atmospheric pollution, do not furnish any clue to the amount of impurity in the atmosphere, except when rain is falling. In other words, no account of the pollution during rainless days is rendered by the rain gauge, and it cannot be assumed that the impurity in the air on a rainless day is going to stay there until rain comes. However, the results are of comparative interest in relation to the amount of rainfall. In many respects, and in spite of a reputation for a smoky atmosphere, Sheffield's atmosphere, according to the report, compares not unfavourably with that of other great manufacturing centres.

CITY OF LONDON LYING-IN HOSPITAL.—At a time when the infant life of the country is a specially important asset it is satisfactory to know that there has been practically no falling off in the subscriptions to the City of London Lying-in Hospital, and that the donations have risen from £420 to £674; but we regret to learn from the report for 1915 that there has been a falling off in nearly all the other items of income. The total income amounted to £6609, being £153 less than in 1914. During the year 1100 women were admitted into the hospital, and of these 1011 were delivered, being 44 less than in the previous year, when the highest number delivered in any year—1055—was recorded. The 1011 women gave birth to 1025 children—viz., 524 boys and 501 girls. In the out-patient department 651 women were delivered at their own homes, as against 849 in 1914. Nine women had twins, 15 children were stillborn, and 10 children died.

THE LANCET.

LONDON: SATURDAY, APRIL 15, 1916.

The Wittenberg Camp.

THIS war has produced some terrible stories, and some of the most terrible, after having been declared to be unimaginable and therefore concocted, have proved to be true. To this category belongs the unspeakable record of the crimes committed by the Germans upon their prisoners of war at Wittenberg; rumours of these crimes had got abroad and were declared to be false because incredible, but the authenticated account leaves the rumours behind. The account is contained in a report by the Government Committee on the Treatment by the Enemy of British Prisoners of War; the report is signed by Mr. Justice YOUNGER, and is based upon evidence collected from prisoners of war repatriated from Wittenberg, and especially from information supplied by the following three officers of the Royal Army Medical Corps, Major PRIESTLEY, Captain VIDAL, and Captain LAUDER. The terrible episode upon which these officers gave their testimony was an epidemic of typhus fever, which broke out at the end of 1914 in the Wittenberg Camp for prisoners of war; whereupon the German staff, medical as well as military, fled from the camp, and from December, 1914, to August, 1915, no direct communication was held between the prisoners and their guards. All supplies for the wretched prisoners were for the future pushed into the camp over chutes, and the food for the hospital—and such food, and such a hospital!—was run in on a trolley over a rail worked by winches. No medical attention was provided by the staff, but in February, 1915, six English medical officers, who were prisoners, were sent to the camp to do the work which the German doctors, to their unspeakable shame, dare not do. Of these six medical men three died, and three have at last been able to tell their tale.

The story as set out in the report is a surprising record of blackguardism. The Germans confined from 15,000 to 17,000 prisoners within wire entanglements upon 10 acres of ground. A large quantity of these prisoners were Russians and were already infected with typhus fever, and the infection was spread among the other prisoners by lice, with which all the prisoners swarmed, for no washing facilities were provided and no soap was supplied. Six weeks after the vile cowardice of the German medical staff in running away from their wretched charges, six prisoner medical officers were deported to the camp, but their strenuous efforts were supported in no way by the director of the German camp. What it was humanly possible to do they did, and their efforts testify to their extraordinary courage, self-sacrifice, and resource. Of the six medical men only three survived, and we hope that their devoted services will not be forgotten. They found the improvised hospital of the camp practically without appliances of any sort. There were no proper bedding and no mattresses; dressings, bandages, and stimulants were wanting; the absence of soap prevented either patients or garments or furniture from being washed. The German authorities received representations of these things with refusal to ameliorate them, and the inhabitants of the locality came down to the encampment to laugh at the coffins as they were removed from the enclosure.

This horrible story will have been read by most of our readers, and makes it necessary that the medical men of other countries than Germany should decide into what sort of relations they propose to enter with the medical profession of Germany when this war is over. Medicine knows no geographical limits or racial distinctions; it is the most essential expression of human service to all human beings. But the doctors of other countries will not sit in friendly conclave with the medical representatives of a country where the responsibilities of human service are regarded as at Wittenberg. The doctors of other countries do not run away from disease; nor would it strike other populations that the bodies of the deserted dead were a good subject for jeers. The doctors of Germany will not for some time be welcome at international gatherings of medicine.

Credulity in War Time.

PSYCHOLOGISTS have often pointed out the antithesis which exists between emotion and intellect. A man in a passion has to a great extent lost his critical faculty; he cannot form a cool judgment; if his situation calls for action of an important character he takes the advice of his friends as to the proper course for him to pursue. A state of war is one in which powerful emotions are raised among the people; and however much we may admire the enthusiasm and driving energy thus derived, we have also from time to time to deplore the failure of calm discrimination, and to admit the readiness to believe in every kind of myth that has a pleasant effect upon the feelings. A crowd is at all times more susceptible to emotion and less endowed with critical faculties than an individual, and it is inevitable that a period of war, which knits a nation together, should also be a period of credulity. In another column will be found a communication on the psychology of rumour made by Dr. BERNARD HART to the Section of Psychiatry of the Royal Society of Medicine. Dr. HART shows that in war-time the prevalence and vitality of rumours are greatly enhanced. At the beginning of the war this truth manifested itself with surprising intensity—the passage of a Russian army through England and the appearance of the angels at Mons, are only flagrant examples of beliefs entertained by large numbers of people, not only without a scrap of reliable evidence in their favour, but in direct opposition to all that calm thought would have suggested. And as war goes on the willingness to swallow

impossible narratives and to put faith in absurd theories does not abate, while it is possible that real mischief may be done if the tendency increases.

A long article appeared recently in the *Daily Chronicle*, entitled "Supernatural Communications in War Time," written by M. MAURICE MAETERLINCK, in which that eminent and charming writer set forth the doctrine that it is possible for civilians at home to get into touch with their friends and relations fighting abroad, by some means of spiritual clairvoyance. It is, we think, singularly unfortunate that a doctrine so much calculated to raise false hopes and to culminate in disappointment and unhappiness should be published with an air of authority by a newspaper of very wide circulation, whose deservedly high reputation only serves to reinforce the error among uninformed minds. M. MAETERLINCK starts out with a statement that is simply untrue, and, indeed, he does not seem to believe his own words. He says that the existence of the faculty of clairvoyance "is no longer seriously denied by anyone who has given some little attention to metaphysics; and it is easily verified by those who will take the necessary trouble." Yet he points out that the medium finds it easier to relate the past than to foretell the future. Efforts in the latter direction appear to have failed. "Errors are almost the rule." "There is scarcely any accuracy of vision." When mediums attempt to predict a general event such as the result of a war, an epidemic, or an earthquake "they almost invariably deceive themselves and us." Moreover, even about the present their statements are not found by M. MAETERLINCK to be accurate. A medium may say that she sees the subject of inquiry "ailing slightly, lying in a deck-chair in a garden of such and such a kind, surrounded by certain flowers and petting a dog of a certain size and breed. On inquiring you will find that all these details are strictly correct, with this exception, that at that precise moment this person, who ordinarily spends his time in the garden, was inside his house or calling on a neighbour." Yet instead of writing down this medium as a fraud, M. MAETERLINCK thinks it worth while to suggest that the scene has occurred at some previous part of the individual's life. Of course it has; we must nearly all have found ourselves taking part in the identical scene at some time of our lives. Such an episode should not be presented to the public as evidence of the spiritual prowess of the medium, even if M. MAETERLINCK does not consider the medium to be condemned by the circumstance that the subject was in point of fact altogether differently engaged from the way in which clairvoyance alleged. M. MAETERLINCK tells us how the medium can give information about a British prisoner in Germany, can describe the fortress or huts in which he is interned, and the appearance of the camp; can do much, in fact, except give the name of the place. Yet this, unfortunately, is the one point that can be immediately tested. The medium tells us with the most marvellous precision all about the things which we cannot verify; she is totally nonplussed by one item, the one which would furnish us with testimony of her veracity. M. MAETERLINCK does not seem to see that she thus becomes unworthy of any notice. He offers one instance of successful clairvoyance of many that he could enumerate if the *Daily Chronicle* were the place to become communicative, the uncivil implication being that his readers could not appreciate the evidence if it was offered. Belief in fetishism he takes as the level of their intelligence, for one of M. MAETERLINCK'S most competent mediums can tell all about a person from inspecting an object which has been handled or touched by that person. The object, he presumes, absorbs like a sponge a portion of the spirit of the person who touched it, and remains in constant communication with him. This leads us straight back to the fetishism of primitive peoples. The uneducated cannot distinguish between a thing and its properties: they think that a part of a man's personality passes into his possessions. We have heard of the African native who would not walk by a river lest a crocodile should seize his shadow on the waters. We have heard of the Chinook who would not tell his name lest it should be stolen. It is very common to find objections in native tribes to being photographed, on the ground that the photographer henceforward possesses some part of the personality of the sitter. Such hopeless mental confusion is natural to the savage. But the British public can hardly have sunk to so gross a form of superstition.

Finally, M. MAETERLINCK, admitting that all which he has written sounds incredible, says that it is hardly more so than radio-activity or the Hertzian waves and other scientific phenomena. Such an argument might be made to justify any absurd folly; for is it not the case that the wonders of nature far exceed those that the most imaginative human mind can invent? Our spiritualists, by using this analogy, merely disclose the barrenness of their own minds, their ignorance of the infinite beauties and marvels of nature. If their minds really need mysteries and wonders let them study science. How ignorant of natural phenomena they must be who set up for our admiration the crude imaginings of their unwholesome minds. And the particular form of credulity which M. MAETERLINCK, a really great litterateur, has elected to advocate has a larger significance and a larger importance than that of merely misleading unfortunate persons as to the fate of their relatives fighting abroad. It is typical of that dangerous mental softness that will not face a fact, and insists upon entertaining not the beliefs that are true but the beliefs that are agreeable. To live in a fool's paradise is fatal, especially when we are at war. To know and recognise the truth, whatever it may be, is the essential attribute of a virile mind: to seek the truth is the highest task of the philosopher. How is it that a great and popular newspaper can lend its authority to M. MAETERLINCK'S rubbish? It almost seems as though it were easier to obtain prominence in our daily newspapers for the lucubrations of charlatanry than for true and useful scientific doctrines. The misfortunes of Europe have brought us back once more to medieval conditions in the realm of action. Let them not

drag us also into the barbarities of medieval thought. At this juncture in our history we have not only to act but to think like men. For there can be little doubt that in the last analysis our existence as a powerful and independent empire depends upon our readiness to accept scientific ways of thinking, to recognise and admit truth on all occasions, and to harden our minds by that intellectual discipline which is no less essential to our welfare than is physical discipline to the soldier.

Annotations.

"Ne quid nimis."

ACUTE POLIOMYELITIS.

IN another column we publish an abstract of the Lumleian lectures on acute poliomyelitis delivered before the Royal College of Physicians of London by Dr. Frederick E. Batten. The first lecture was devoted to the epidemiology and pathology of the disease, the second to the experimental researches which had been carried out, and the third to the clinical consideration of the subject. The lecturer's idea throughout was not to introduce new theories, but to discuss in a way that would be valuable, both by clearness and inclusiveness, a condition which is obscure in many of its manifestations and which has proved particularly dangerous on occasion to our troops. The clinical features were particularly well described. Dr. Batten adopted the grouping suggested by Wickman, which is based on an anatomical distribution—viz., (1) the spinal form; (2) the bulbar, pontine, and mid-brain form; (3) the cerebral form; (4) the cerebellar form; (5) the neuritic form; (6) the meningitic form; (7) the abortive form. This classification indicates the variety of symptoms which may occur. In the lectures attention was drawn to the phenomena which present themselves when different muscles are involved. One variety consists in the paralysis of the neck muscles without affection of the bulb or shoulder muscles. Dr. Batten pointed out that weakness of the neck muscles makes it impossible for the patient to walk, owing to the power of balancing being lost. The meningitic form is one of the most interesting groups, and the meningitis is indicated by the presence of lymphocytic cells in the cerebro-spinal fluid, but the symptoms frequently lead to errors in diagnosis. The remarks on treatment are well worthy of attention. Rest was particularly insisted on as the most important factor. The principles by which physiological rest can be secured to the muscles were considered, and Dr. Batten emphasised the importance of placing the paralysed muscles into the "zero position." This can be carried out by placing the paralysed limb or limbs in celluloid splints, accurately fitted to the limb. These splints were first introduced into this country by Mr. H. J. Gauvain. They are light but firm, and their efficacy in giving support to diseased joints is familiar to those who have seen them in use at Sir William Treloar's Cripples' Home at Alton. In poliomyelitis, whilst keeping the paralysed muscles in a normal zero position, other muscles which may have been more or less affected must be re-educated to resume their normal function. If this treatment is adopted at an early stage of the disease, not only will recovery be facilitated, but deformities will in a great measure be prevented. These lectures should spread the knowledge of acute poliomyelitis in a valuable way.

THE DIAGNOSIS BETWEEN POWDER EMBEDDED IN THE SKIN AND LEAD PARTICLES.

THE present trench warfare has been attended with a great many wounds due to the débris of projectiles of high velocity which are broken up on striking the parapets. When a bullet strikes a hard stone the greater part of the force is converted into heat, the lead is fused and, with the débris of the sheath, is projected in fine droplets, which the resistance of the air makes smaller and smaller. At a meeting of the Académie de Médecine of Paris M. Ducellier, radiologist of the Saint-Roch Hospital, Nice, has called attention to the importance of the resulting injuries. The particles are so small that their power of penetration is slight, and they are easily arrested by the clothes. Hence the wounds are mostly on the face or hands. They usually take the form of several small wounds surrounded by a bluish more or less circular zone according to the greater or lesser obliquity of the skin to the line of flight. The discolouration is due to penetration of the skin by small particles of lead, and these may be mistaken for powder granules. The diagnosis is important, because if the wound is in the hand the question may arise whether the soldier has injured himself voluntarily—a serious offence. The circumstances of the wounding will usually enable a correct conclusion to be drawn, but for absolute certainty it is necessary to demonstrate the nature of the particles embedded in the skin. If they are powder, a firearm has been discharged at close quarters; if lead, all possibility of voluntary mutilation is excluded. Removal of a piece of skin and chemical tests would settle the question, but this method may not be available at the front. The X rays, which are always at hand, thanks to the motor-cars equipped with the apparatus, will at once solve the problem. When the discolouration is due to powder the plate shows normal transparency of the tissues, but when the spots are clearly visible they are due to particles of the projectile. But it is necessary to take a plate and not trust to radioscopy. The screen has not the sensitiveness of the plate, and fails to show metallic particles of some size.

COMPULSORY TREATMENT OF VENEREAL DISEASE.

IN the Majority Report of the Swedish Royal Commission on Venereal Disease a scheme has been outlined with the object of rendering treatment of venereal disease compulsory under certain conditions. In this scheme these four main principles have been kept in view: 1. It must secure the sanitary objects aimed at, it must not give the public a false sense of security against the dangers of immorality, and it must not frighten patients from seeking medical treatment voluntarily. 2. It must give satisfaction morally. Thus, it must not weaken the defences against immorality or interfere with the development of public morals in the right direction. 3. It must not discriminate between the various classes of society, the greatest possible equality of treatment for the two sexes must be secured, and opportunities for arbitrary action by its administration must be reduced to a minimum. 4. It must not curtail personal liberty unnecessarily

it must not give an opening to spies and blackmailers, and it must not entail great administrative machinery or expense. On the basis of these principles measures have been proposed giving the sanitary authorities powers to make treatment compulsory for patients notified by medical men as being a source of infection, for persons convicted under the vagrancy law of professional immorality, and for persons accused of certain crimes and suspected of being infected with venereal disease. Under the present system of regulation in Sweden it is impossible to take summary measures except in the case of the professional prostitute. According to the Commission's scheme, not only would the "whole-time" prostitute be subject to compulsory treatment, but this could also be prescribed for the occasional prostitute and other women infected with venereal disease, as well as for men known to be sources of infection. It is also pointed out in this Majority Report that under the present system the syphilitic "whole-time" prostitute is kept in hospital for treatment only as long as there are infectious manifestations of the disease. According to the Commission's scheme, such a patient would be kept under observation as long as the disease was infectious, whether there were any demonstrable symptoms or not. In a Minority Report, signed by Professor Johansson and Hrr. Westerberg, compulsory measures against infectious venereal disease are described as superfluous and unjust. The signatories say that the majority's proposals entail notification of venereal disease and tracking down sources of infection, steps which they consider harmful as well as ineffective. In defence of this opinion they point out that at present many infectious patients seek medical aid voluntarily, whereas compulsory treatment would prejudice hospitals and doctors with this class of patient, who would shun them. Further, it is urged, the Commission's scheme is involved, and open to the abuses of circumlocution, mistakes of identity, and false notification. In the campaign against venereal disease compulsory measures should be directed rather against institutions such as brothels, which are perfect hot-beds of infection, than against the individual. Thus, it is evident that, as with so many other proposals by the Swedish Royal Commission on Venereal Disease,[1] this particular scheme is regarded with disfavour in certain quarters.

THE VALUE OF SCIENTIFIC DENTISTRY.

Dr. F. J. Waldo, coroner for the City of London and the Borough of Southwark, embodies a variety of matter in his annual report of inquests held by him during the past year, and his remarks on the value of scientific dentistry are very timely. The connexion between dentistry and inquests is not at first apparent, but a coroner holds inquiries upon occasions when evidence pointing to starvation gives reason to suspect an "unnatural" death, and Dr. Waldo refers in his report to examples of deaths due to lack of teeth or to the presence of septic stumps only—of death, that is to say, which might have been averted by the dentist's care and by the supply of artificial teeth. He relates also that a report of an inquest upon a case of this class, held by him, was read with a most gratifying result by Mr. Edwin Tate, who by a gift of £5000 thereupon inaugurated a fund to be administered at St. Bartholomew's Hospital for the provision of artificial teeth for necessitous and deserving out-patients. We congratulate Mr. Tate upon his generosity and the coroner upon having prompted him to set an example which we hope may be followed by others. Well-to-do persons, who so easily procure for themselves artificial teeth when those fail with which nature endowed them, do not realise that for their poorer neighbours inability to masticate their food implies not merely discomfort, but loss of health, and even in extreme cases of life itself. No doubt other hospitals would gladly profit by similar gifts to that which St. Bartholomew's Hospital has received. Although artificial teeth may be too expensive gifts for hospitals to provide for their patients out of their ordinary funds, a sum of not many hundred pounds per annum, earmarked for that purpose by their givers, would supply a substantial number of sets to patients for whom it is too late to recommend conservative measures in dentistry.

THE CONSERVATION OF INFANT LIFE IN SCOTLAND.

THE infantile death-rate in Scotland is about the same now as it was 60 years ago. This matter of serious national importance receives attention in a report by Mr. D. W. Kemp to the Convention of the Royal Burghs of Scotland,[1] which ancient and honourable body represents two-thirds of the population. A chart, prepared by Dr. James C. Dunlop, shows a curve of the infant mortality in Scotland for the period 1855–1915. In the report is emphasised this most unsatisfactory and disappointing state of affairs, especially considering the large sums of money spent in public health, in dealing with slums and housing, the improved food and milk supplies, as well as the advances in medical and obstetrical science. Mr. Kemp adds: "But for the numerous voluntary agencies working for the welfare of infancy during the last decade, the death-rate would probably have been much higher." In the report are reproduced from THE LANCET[2] a leading article and a letter concerning the preservation of infant life. Our correspondent's idea, it will be remembered, was to enlist the active sympathies of the public, the personal interest in a particular baby being stimulated by monthly bulletins or otherwise. We trust that Mr. Kemp's report, which is to be circulated all over Scotland, will accelerate the efforts being made to reduce the deaths of infants and to promote child and maternity welfare.

POISONING BY DAFFODIL BULBS.

AT a recent meeting of the Pharmaceutical Society in Edinburgh a paper was read by Mr. W. G. McNab in which he described the uncomfortable consequences of the error of a cook who, it would seem, was sadly ignorant of the botany of the kitchen garden. Briefly, the cook, in concocting a *soupe à l'oignon*, had mistaken the bulbs of the daffodil for those of the onion, and neither the appearance of the bulbs nor her tearless eyes while preparing them for the pot told her that anything was wrong. The soup was served, and every member of the family, cook as well, experienced symptoms of nausea followed by violent vomiting

[1] Third Report on Infant Mortality in Scotland, and the Executive Meetings of the National Association for the Prevention of Infant Mortality and the Welfare of Infancy, by D W. Kemp (Assessor for Dornoch), Representative of the Royal Burghs Convention to the National Association.

[2] THE LANCET, Jan. 29th, 1916.

and diarrhœa. Thereafter on three consecutive occasions when the family had soup for dinner the same thing occurred. It was not until an investigation revealed the facts that the box in which the domestic onions were stored had long been empty and that the cook had been drawing her supplies from an adjacent box containing garden bulbs that the cause of the trouble was discovered. Judging from like experiences related in the course of the discussion which followed the reading of the paper, similar mistakes are not uncommon, and it might therefore be wise if medical practitioners called in to diagnose obscure cases of family sickness would cross-examine the cook. Daffodil bulbs contain an alkaloid the action of which, according to authorities, varies as to whether the alkaloid is extracted from the flowering bulb or from the bulb after flowering. Thus in the former case the alkaloid produces dryness of the mouth, checks cutaneous secretion, dilates the pupil of the eye, quickens the pulse, and slows and weakens the heart contractions. On the other hand, the alkaloid from the bulbs after flowering produces copious salivation, increases cutaneous secretion, contracts the pupil of the eye, produces slight relaxation of the pulse, and slight faintness and nausea. Apparently there is no record of a case of fatal poisoning from daffodil bulbs.

INFANTILE SYPHILIS: AN ANALYSIS OF 100 CASES.

Dr. B. S. Veeder and Dr. P. C. Jeans bring out some instructive points in relation to infantile syphilis in a paper in the *American Journal of Diseases of Children* for March. Of congenital syphilis they recognise four types: fœtal syphilis includes the majority of abortions and premature births due to syphilis; infantile syphilis includes cases in which the child is born apparently healthy but develops signs of syphilis within a year; late or tardy syphilis embraces those in which signs of syphilis develop after infancy; and in the latent type are grouped those children, apparently healthy, but in whom the Wassermann reaction is positive. It is with the second group only that this paper deals. These infants are taken to the medical practitioner because of either coryza or rash in the large majority of cases, occasionally for epiphysitis. Rash was present in 77 per cent., rhinitis in 74 per cent.; the two are not always associated. Epiphysitis occurred in 14 cases. The spleen was enlarged in 82, and it is stated that, where this is the case in a child under 6 months old, in absence of any exudative diathesis, syphilis is probable. In 60 the weight was below normal, but in 10 it was above. The Wassermann reaction was positive in 92·6 per cent. In 81–85 per cent. the symptoms began in the first two months. As regards prognosis, this is bad. There is a mortality of 40 per cent. in spite of all treatment. All the deaths occur in the first six months of life. It is significant that treatment appears to have no effect, though neosalvarsan given intravenously (a proceeding which seems to be well borne) into the external jugular vein causes rapid disappearance of the rhinitis. Nutrition has the greatest influence upon the chances of survival. This is strikingly brought out by a comparison of infants breast-fed and those artificially fed. Of 42 infants who were breast-fed for a period longer than three months only 3 died (7·1 per cent.), whereas of 17 breast-fed only for a month 9 died (52·9 per cent.).

A DIETETIC VIEW OF THE TAX ON AERATED WATERS.

WATER in its aerated form is clearly a luxury, and the addition of carbonic acid gas to water justifies a tax according to this view. The tax will diminish the consumption of all aerated beverages, and a return to the use of plain water will ensue. For the whole community, teetotal or otherwise, a beverage that is not carbonated, and which is therefore not taxed, will be cheaper. But the physiological action of a water briskly effervescing with carbonic acid gas is different from that of a plain water or of a water which is not effervescent, and a general return to plain water therefore raises some dietetic questions. Apart from æsthetic considerations, questions, for example, of its acid attractiveness, carbonated water exerts, according to some observers, a specific effect in the stomach. Aerated beverages in most cases promote the chemical processes of digestion by causing an earlier and more abundant secretion of gastric juice, while the carbonic acid gas may also act as a stimulant to the movements of the stomach, and thus aid the mechanical process of digestion. Possibly the effervescent action of the carbonated water causes a circulation or distribution of the food particles. In England the introduction of cheap soda-water was largely responsible for making whisky a popular alcoholic beverage, and incidentally the public were unconsciously basing their preference of aerated water to still water on the agreeable effects on digestion which in so many cases an aerated beverage produces. It is well known, moreover, that an effervescing alcoholic beverage is a more rapidly diffusible stimulant than a still fluid. It is important, however, to remember that the duty on table water is designed to apply not to the manufacture of these waters but to their sale, which means that the tax is charged separately on the quantity contained in a separate bottle, the term "bottle" including any reservoir. Premises for manufacture will require to be licensed under a fee. For domestic purposes, however, the manufacture of soda-water as in a seltzogene or similar vessel, with which most of us are familiar, will be neither taxed nor is it intended that a licence charge be imposed. The definition for "table waters" makes this clear, for they are described as "any aerated waters and any beverages sold or kept for sale in bottles other than (*a*) any liquor for retail sale of which an Excise licence is required; and (*b*) syrups or other liquors intended to be consumed in a diluted form."

THE ARMY MEDICAL CIVILIAN RESERVE.

Mr. Rickard W. Lloyd has brought to our attention a letter written by the late Mr. C. B. Keetley 11 years ago which is of considerable topical interest at the present moment. The letter was addressed to a certain number of medical men entirely upon Mr. Keetley's own responsibility, but he had assured himself that the Director-General of the Army Medical Staff (then, as now, Sir Alfred Keogh) would view with the greatest approval the formation of a Voluntary Medical Reserve. Mr. Keetley's straightforward letter is characteristic of the man.

The Director-General of the Royal Army Medical Corps has pointed out that, in the case of a great war, he would be the only member of that Corps left in the kingdom. There would be no trained Medical Reserve. There would be the Volunteer medical officers, but they would have their own

duties. Lord Roberts said on Saturday, speaking of the army in general: "There is a great deal more necessary, and that is that, in addition to the army and reserve forces, there should be a great potential reserve of the whole nation." The Director-General is most anxious to see a great potential reserve of the medical men of the nation. It seems to me that this could be furnished without any great sacrifice on anyone's part. Medical men possess medical knowledge to begin with. They have not to learn to shoot. From a soldiering point of view, therefore, a doctor is comparable to a gamekeeper, or, better still, to a Volunteer who has made rifle-shooting his hobby. All the medical man needs is instruction in the official and routine duties of a medical officer in charge of a hospital or of a body of troops. I am assured by the highest authorities that this could be given in a dozen lessons or less. No drill is required. I think that in the case of a large number of medical men who are not officers of Volunteers, that it would not ask too much of their patriotism for them to be willing to receive these lessons. All medical men who thus qualified themselves could be organised into a corps with strictly local subdivisions. *In the case of a great war no member of this corps should be expected to do army medical duties at any great distance from his own locality, or without proper payment.* No expense in uniform would be required. ..... Among the thousands of members of such a reserve medical corps there would be, when war broke out, some hundreds who would be both qualified and willing to serve abroad—in fact, to act as a reserve to the Royal Army Medical Corps abroad. Without the organisation I have indicated, and without the lessons in time of peace, these hundreds might be willing, but they would be very imperfectly qualified.

PS.—I am writing this entirely on my own responsibility, but not without first assuring myself by consultation with the highest army medical authorities that the scheme would be received with favour. The enthusiasm and energy of the present Director-General of the Royal Army Medical Corps are well known, and his intense desire to establish a proper reserve. In fact, his views with regard to the Royal Army Medical Corps are precisely those of Lord Roberts with regard to the army in general. I am sure you will agree with me that the country is fortunate in possessing such men at this juncture, and that it is our duty as individuals to second their efforts.

Mr. Herbert Chambers, writing from Goldhawk-road, Hammersmith, tells us that Mr. Keetley's letter resulted in 40 men in the Hammersmith district of London interesting themselves in the movement, who at the termination of the course had mostly obtained a rough idea of regimental officers' duties. "The Territorial scheme," he adds, "was shortly after introduced and completely smothered individual effort."

THE INFLUENCE OF COLD UPON THE TRICHINOUS LARVÆ.

PREVIOUS to the research conducted by Mr. B. H. Ransom, the author of a pamphlet dealing with this subject,[1] it had been generally accepted that the larvæ of trichinella spiralis were very resistant to cold. Extended investigation was made into the matter. Quantities of trichinous meat varying in weight from a few grammes to nearly 400 lb. were frozen and kept for periods varying from a few minutes to 57 days at various temperatures below the freezing point of water. The meat on removal from the freezer was generally allowed to thaw slowly at ordinary house temperatures. Frozen meat after thawing was artificially digested and examined microscopically on a warm stage and the number of inactive and active trichinæ were recorded. Trichinous meat from the same carcass as the frozen meat was used for controlling the effects of the process of digestion. Another portion of frozen meat, after thawing, was fed to test animals, in most cases white or hooded rats. Unfrozen meat from the same carcass was fed to control test animals. The test animals as they died, or after about a month if they lived so long, were examined for trichinæ. About 30,000 trichinæ were examined from artificially digested frozen and unfrozen meat, and over 500 test animals and control animals were fed and examined. A considerable portion of the trichinæ in meat exposed to a temperature of about 15° F. for periods of 23 days or less survive and are quite lively after thawing, but such meat frequently fails to infect test animals. Some of the trichinæ in meat exposed to a temperature of about 10° for periods of 57 days or less generally survive. A temperature of 10° is more injurious to trichinæ than a temperature of 15°, but like the latter its effects are uncertain, although meat exposed to it for 14 days or longer has generally failed to produce infestation. No infestation has been produced by trichinous meat exposed to a temperature of about 10° for 20 days or longer. Temperatures of 5° F. or lower profoundly affect the vitality of trichinæ. Only a very small proportion survive an exposure of more than five days. Artificial digestion of trichinous meat has no apparent effect upon the activity or structure of the trichinæ. In the practical application of refrigeration as a means of destroying the vitality of trichinæ meat should be refrigerated at a temperature not higher than 5°F. for not less than 20 days, a period which allows a probable margin of safety of nearly 10 days. The employment of higher temperatures of refrigeration as a means of destroying the vitality of trichinæ is not justified in the light of our present knowledge, because of the uncertainty of the effects of such temperatures. Whether temperatures higher than 5°F. may be safely employed by lengthening the period of refrigeration remains to be determined.

[1] Effects of Refrigeration upon Larvæ of Trichinella Spiralis, by B. H. Ransom, Chief of the Zoological Division, Bureau of Animal Industry, Journal of Agricultural Research, Department of Agriculture, Washington, U.S.A.

WE regret to announce the death of Sir Alexander Russell Simpson, professor of midwifery and diseases of women in the University of Edinburgh, which occurred on April 6th in Edinburgh as the result of an accident. An obituary notice will appear in a later issue.

THE death has also occurred, we are sorry to say, of Colonel Arthur E. J. Barker, A.M.S., professor of surgery and clinical surgery in University College of London, and surgeon to University College Hospital, who died while discharging military duties.

Mr. Hugh M. Rigby, M.S. Lond., F.R.C.S. Eng., has been appointed a consulting surgeon to His Majesty's Forces in France with the rank of Colonel, A.M.S.

THE library and offices of the Royal Society of Medicine will be closed from Thursday, April 20th, to Tuesday, April 25th, both days inclusive.

ROYAL INSTITUTION.—Among the day lectures to be delivered after Easter the following are announced:—Professor Charles S. Sherrington (two): Harvey and Pavloff. Dr. T. M. Lowry (two): Optical Research and Chemical Progress. Sir Ray Lankester (three): Flints and Flint Implements. Professor W. H. Bragg (two): X Rays and Crystals—(1) New Methods of Research; (2) First Results and their Applications (the Tyndall lectures). The Friday evening discourses will be resumed on May 5th. Sir J. Mackenzie Davidson: Electrical Methods in Surgical Advance. Professor Charles G. Barkla: X Rays. Mr. Ernest Clarke: Eyesight and the War.

REPORT OF THE COUNTY MEDICAL OFFICER OF HEALTH AND SCHOOL MEDICAL OFFICER OF LONDON FOR 1914.

HEALTH OF THE METROPOLIS IN WAR-TIME.

THE annual report of Dr. W. H. Hamer for the year 1914 has recently appeared.[1] A third year's experience of the policy of coördination as applied to the administration of public health and elementary education in London materially strengthens the confidence we have before expressed in the principle involved.[2] We should be prepared to advocate its extension to other communities of smaller but still sufficient size provided that suitable administrative arrangements could be secured. Careful reading of the volume before us conveys the impression that, in spite of the distracting influence of the European War, the highest possible efficiency has been maintained throughout the year in those departments of the Council with which our profession is concerned. In no respect have the interests of public health or education been sacrificed to existing emergencies.

The arrangement of subject matter adopted in the two preceding reports has been continued in the present volume, the contents of which may be indicated as follows: Part I. discusses the question of metropolitan public health generally, with particular allusion to the degree in which it has been affected by the war. Part II. gives account of the advisory action of the medical officer in his capacity as school medical officer; it also furnishes particulars of the administration of the Council as the education authority for London.

PART I.—*Public Health.*

The efficiency of sanitary administration in London must have been severely tested by the conditions of war obtaining since the autumn of 1914. On the outbreak of hostilities many of the borough medical officers of health were accepted for service in connexion with the housing and feeding of troops, the maintenance of sanitary conditions, and the adoption of precautions against disease. These services are rendered under military direction and are additional to the duties ordinarily performed by officers of a sanitary authority. It is gratifying to learn that in spite of the unprecedented conditions referred to, and notwithstanding the ever-pressing necessity of meeting exceptional demands for medical service, a satisfactory amount of preventive work has been accomplished by the sanitary authorities and their officers, central as well as local.

Vital statistics.—Movement of population.—Commenting on the vital statistics of London the medical officer again invites attention to the question of population movement as affecting the age constitution of the community. In the annual report for 1912 evidence was presented showing the persistence of a distinct outward flow from London of young married persons and their families. Again, in the report for 1913 the importance of local migration was shown, firstly by comparing London with the provinces in respect to age constitution of their population, and subsequently by similarly comparing the areas north and south of the Thames. It was further pointed out that London attracts females at the ages of 25–35 in greater numbers than males. The striking differences of the figures given accentuate the necessity of still bearing in mind the changes in age constitution of the community which exercise so marked an influence in London.[3] In particular regard should be had to the effect of these changes upon the rates of births, marriages, and deaths, as well as upon the rates of infantile mortality.

Antenatal and postnatal mortality.—In further discussing the question of loss of life among infants, the medical officer discriminates between the group of causes attributable to antenatal (or natal) conditions, including premature birth, atrophy, and marasmus on the one hand, and the group of postnatal causes constituting the large category of "general diseases" on the other. After eliminating, for specified reasons, the deaths from diarrhœa and the common infectious diseases, and dividing the last ten years into quinquennial periods, it is indicated that the prenatal group of causes shows a relative increase from 48·2 per cent. in the first period to 51·4 per cent. in the second, whilst the postnatal group shows a considerable decline throughout. A further remarkable point respecting the assignation of cause of death is this, that the death-rate from premature birth has increased from 10·3 per 1000 in 1871–5 to 18·7 in 1906–10, whilst the death-rate from atrophy and debility has correspondingly diminished. It appears doubtful, however, whether premature births are relatively more frequent now than formerly; and it is possible that the discrepancy is capable of explanation by assuming considerable changes of fashion in nomenclature. With reference to the happily persistent decline of infant mortality, it is evident that its explanation might be sought not in any local but in some common influence operating over a wide area. The effect of migration upon changes in the social status of present-day parents as compared with those of 50 years ago must certainly be regarded as influencing infantile mortality. The decline in that mortality has resulted in part from definite improvement in "environment," and in part from interchange between London and the country generally of certain elements of the population. To this latter factor almost as much importance should be attached as to the former.

Tuberculous disease: provisions for treatment.—The scheme of the Council for the treatment of tuberculosis has been approved by the Local Government Board.[4] In formulating this scheme the Council was animated by the desire to ensure the coöperation of all existing medical agencies, so as to provide that the patient's progress should be supervised from the date of his attack until the completion of treatment, and that he should receive medical care even beyond that period. An advisory board has been appointed consisting of representatives from the great hospitals, whose duty consists in securing uniformity of standard in the selection of patients for treatment—a rota of physicians being nominated by them for the examination of exceptional cases. Considerable difficulty was at first encountered in obtaining suitable residential accommodation, and that difficulty has been accentuated since the outbreak of war. But in spite of this the Council has succeeded in keeping pace with the demand, and in the case of children has prevented the accumulation of a long "waiting list." They have secured accommodation for residential treatment to the extent of 160 hospital beds, 240 beds in sanatoriums, and 150 children's beds; and negotiations have been opened with the Metropolitan Asylums Board for further accommodation in future.

Meningeal and abdominal tuberculosis: question of diagnosis.—In his annual report for 1913 the Registrar-General comments on the evidence that abdominal tuberculosis causes a relatively low mortality among children in London, whilst meningeal tuberculosis is more destructive there than elsewhere. He raises the question whether this is in accordance with fact. It is common knowledge that the mortality from abdominal tuberculosis tends to rise in years of exceptional fatality from diarrhœa, and it is credible that this may be due to the erroneous return as tuberculous of some deaths not really caused by that infection. If the deaths so certified now are not all due to tubercle, this would probably have been still oftener the case 30 years ago, which would help to account for the existing low mortality in London, where there is reason to believe that death certification is at its best. With the object of ascertaining whether any reduction of this mortality has followed the County Council's treatment of tuberculous milk Dr. Hamer has prepared an instructive diagram, from which it appears that in Manchester where action against tuberculous milk was commenced nine years previous to 1908, when similar action was initiated in London, the decline of tuberculous mortality is actually less marked than in the metropolis. This behaviour of the rates lends support to the theory that the fall experienced is mainly due to improvements in medical diagnosis and consequently in death certification. The medical officer considers it premature to ascribe the recent decline of tuberculous mortality among children to the promotion of special measures for the protection of the milk-supply against contamination.

Scarlet fever: etiological considerations.—During the year London experienced a considerable increase of scarlet fever, which formed part of a general prevalence throughout the country. The London attacks were more numerous than in

any year since 1907. In the report for 1911, pp. 62, 63, special study was recorded of the seasonal prevalence of fleas in relation to the spread of scarlet fever, and the subject is again discussed in the present report. Respecting the etiology of this disease certain facts have been established. We know, for example, that scarlet fever is wont to exhibit major curves of prevalence in which the interval between crest and crest is from 6 to 8 years. Accordingly a wave-crest was due to appear about the year 1914, and, as a matter of fact, such a wave-crest did actually then occur. Many years ago Dr. G. B. Longstaff pointed out that scarlet fever displays a remarkable inverse correlation with rainfall—dry years, and particularly cycles of dry years, corresponding to cycles of excessive incidence of this disease. The subject is still under official consideration. Whilst admitting that the curves of scarlet fever and flea prevalence tend to rise from a low level at the beginning of a six-year period to a high level at its end, Dr. Hamer deprecates the formation of a precise conclusion until the results can be examined for a longer series of years.

Typhoid fever: changes of nomenclature.—Early in 1914 a "heightened prevalence" of typhoid fever was reported in London. The increase was limited to the spring, and it is noteworthy that there was practically complete absence of the usual rise in the autumn of that year. A somewhat wide distribution of attacks was revealed by inquiry, which once more gave rise to suspicion that food infection was the cause of mischief. Information was collected respecting 400 out of 789 attacks notified, from which it appears that in nearly half the cases infection was conveyed by means of fish or molluscs, coming from distant polluted foreshores or from remote estuarial waters. Criticising certain of the latest theories of causation advanced by Koch and his opponents, Dr. Hamer points out in what respects they severally fail to account for the recent spread of typhoid. The history of the disease in London indicates that typhoid particularly affects that section of the population which buys and eats what has been termed "trash" in the streets. Sometimes purchasers of "haporths" of fried fish, sometimes eaters of mussels, more rarely of cockles, are chiefly affected. On the outbreak of hostilities fears were expressed lest London should be infected by soldiers or refugees coming from the seat of war. That these fears were groundless has been proved by subsequent experience. While the low rate of typhoid fever incidence in London is highly satisfactory, it is probable that to some extent this is due to alterations in nomenclature. It is noteworthy that during the last 14 years in which deaths from appendicitis have been separately tabulated, the mortality from that disease has steadily increased, and at present the deaths thus certified are three times as numerous as those from typhoid fever. The fact is important, in this connexion, that the cases notified as typhoid in recent years are by no means always examples of that disease. The Metropolitan Asylums Board reports show that the proportion of cases erroneously certified before admission as typhoid has never been lower than 17 per cent., whilst in three recent years it has varied from 37·9 to 40·5. There can be no doubt, therefore, that considerable alteration of fashion has taken place as regards nomenclature in the case of typhoid-like diseases. If due allowance be made for this fact the estimate of the extent of the decline accredited to typhoid fever in London will have to be somewhat modified.

Cerebro-spinal fever and influenza.—The number of cases of cerebro-spinal meningitis notified in 1914 was the lowest on record. Of the 73 cases reported only 61 could be regarded as definitely due to that disease. In the same period 58 deaths were registered as from cerebro-spinal or post-basic meningitis, including a number of fatal cases that were not certified as such until after death. In 1907 an outburst of cerebro-spinal meningitis occurred in Glasgow in the course of which 1238 cases with 838 deaths were reported, whilst in Belfast some 725 cases with 548 deaths were recorded during the 18 months ended June, 1908. Sporadic cases of cerebro-spinal meningitis appear at certain seasons of each year in all large communities, and this endemic form when occurring in young persons is usually designated post-basal meningitis. In regard to infectivity and severity, the features of this type of the disease differ materially from those of the epidemic variety. The epidemic prevalence of the disease occurs in waves of varying intensity, and is governed by a complexity of conditions as yet imperfectly understood. During the previous seven years cerebro-spinal meningitis had not assumed epidemic proportions, but towards the end of 1914 cases were reported from various parts of the country, and in the early months of the following year the disease may be said to have assumed an almost epidemic character in London. Evidence of the increasing prevalence of the disease was primarily derived from the Naval Depôt at the Crystal Palace. During the first ten months of 1914 only scattered cases of cerebro-spinal meningitis were notified in London; then at the end of the year came an outburst of influenza with pneumonic complications, and close on its heels the prevalence of cerebro-spinal fever. With a view of throwing light on the possible relationship between these two conditions the services of the borough medical officers of health were enlisted. As a result of their investigations it appears that during the period from Jan. 1st to May 22nd, 1915, when influenza was prevalent, 523 cases of cerebro-spinal fever were notified. Among 462 of these cases there was a history of influenza in 37 instances, and in 27 of these the patient was said to have suffered from influenza within a week of the onset of cerebro-spinal fever. Catarrh, sore throat, and "colds" were noted as having affected 70 patients prior to attack by cerebro-spinal fever, and 10 patients had recently suffered from pneumonia. Contact with cases of influenza colds was noted in 66 instances. Dr. Hamer next proceeds to examine the main question, whether the number of cases of cerebro-spinal fever giving a history of recent attack by, or contact with, influenza was greater than might have been expected as a matter of chance. His provisional conclusion is that some definite relation probably exists between the two diseases. "This presumption" is, in his opinion, "materially strengthened when regard is paid to the large number of cases of cerebro-spinal fever giving a history of contact with sufferers from influenza."

(To be concluded.)

THE SERVICES.

ROYAL ARMY MEDICAL CORPS.

THE undermentioned Majors to be temporary Lieutenant-Colonels whilst commanding Casualty Clearing Stations:—W. D. C. Kelly and D. L. Harding, D S.O.

The undermentioned are granted temporary rank whilst commanding Field Ambulances:—To be Lieutenant-Colonel: Brevet Lieutenant-Colonel FitzG. G. FitzGerald, Major B. F. Wingate, Major M. F. Grant, Major G. A. K. H. Reed, Major G. H. Richard, and Major J. Fairbairn. To be Major: Captain V. T. Carruthers.

Major (temporary Lieutenant-Colonel) T. S. Dudding relinquishes his temporary rank on ceasing to command a field ambulance.

Major (temporary Lieutenant-Colonel) William M. B. Sparkes relinquishes his temporary rank on vacating the appointment of Assistant Director of Medical Services of a Division.

Temporary Major E. W. H. Groves, Captain, R.A.M.C. (T.F.), relinquishes his temporary commission.

Temporary Major A. Lingard to be temporary Lieutenant-Colonel.

Captain W. R. O'Farrell is restored to the establishment.

To be temporary Captains: H. B. Maunsell, J. R. Currie, and A. P. Chown (C.A.M.C.).

The undermentioned temporary Lieutenants to be temporary Captains: E. S. Moorhead, A. Riley, H. A. Haig, A. W. Matthew, H. T. L. Roberts, A. M. Pryce, F. W. Wesley, G. A. Birnie, W. C. C. Kirkwood, J. H. Wilkinson, E. H. Rainey, J. A. D. Radcliffe, L. D. Shaw, W. W. Scott, A. J. A. Peters, T. G. Brown, R. Slaney, C. F. Drew, W. T. Smith, A. MacKintosh, T. Ferguson, C. J. Scholtz, B. W. Gonin, O. S. Kellett, W. E. P. Phillips, F. S. Turner, M. J. Fraser, H. Owen, H. R. Brown, J. R. Mitchell, H. Dyer, W. A. Rees, E. Rogerson, R. B. Lucas, W. H. Godby, N. E. Packer, C. O. Donovan, R. B. Carter, E. P. Blashki, J. L. Digby, N. Mc. A. Gregg, N. W. Broughton, S. W. G. Ratcliff, C. Farranridge, A. W. Raymond, W. H. Allen, T. J. J. Curran, F. A. L'Estrange, H. Dudley, J. M. McLachlan, H. R. Souper, C. Burnham, H. E. Clutterbuck, S. Williams, R. E. F. Pearse, W. N. Soden, J. W. Robertson, N. Smith, J. B. Hunter, A. Renshaw, H. J. Penny, J. J. O'Neill, B. W. Wibberley, P. P. Noble, G. R. Pennant, T. W. David, G. W. Parry, A. R. Gunn, A. R. Finn, R. S. Morshead, G. M. C. Powell, G. W. FitzHenry, T. H. Whittington, C. O'Brien, and W. Garton.

The undermentioned temporary Honorary Lieutenants to be Temporary Lieutenants: W. H. Marshall and E. I, Davies.

The undermentioned to be temporary Lieutenants: G. E. Dodson, W. J. May, G. B. King, J. N. Glaister, W. A. Curry, D. S. Taylor, V. Wallace, W. J. Tulloch, C. J. McCarthy, C. Cairnie, W. K. Bell, C. V. Kebbell, R. Orr, C. M. Eadie, D. Rees, and W. F. Cornwall.

The undermentioned temporary Lieutenants relinquish their commissions: L. R. G. de Glanville, H. S. Vivian, C. R. Wright, J. W. Farrar, D. F. Finlay, L. B. Daly, T. C. Last, R. N. Thomson, J. R. Wortabet, H. H. R. Bayley, L. W. K. Scargill, A. E. Goldie, N. D. Mackay, E. H. Kenny, K. G. Colquhoun, C. T. Stephen, H. C. Colville, A. Pryde, F. W. Harrowell, S. Caplan, P. A. M. Green, J. A. Brown, H. J. Moon, L. M. Piggott, and E. Greene.

SPECIAL RESERVE OF OFFICERS.

Royal Army Medical Corps.

Cadet Sergeant-Major G. Morris and Cadet Sergeant J. A. Crawford, Edinburgh University Contingent Officers Training Corps, to be Lieutenants (on probation).

Temporary Lieutenant O. D. Price, from the Royal Army Medical Corps, to be Lieutenant. Ex-Cadet Sergeant E. W. Mann, Belfast University Contingent, Officers Training Corps, to be Lieutenant (on probation).

TERRITORIAL FORCE.

Army Medical Service.

Lieutenant-Colonel A. D. Sharp, from West Riding Field Ambulance, to be Assistant Director, Medical Services, West Riding Division, with the temporary rank of Colonel.

Lieutenant-Colonel D. Smart, from the Sanitary Service, to be Assistant Director, Medical Services, West Lancs. Division, with the temporary rank of Colonel.

Lieutenant-Colonel L. J. Blandford, from the Sanitary Service, to be Assistant Director, Medical Services, 1st Mounted Division, with the temporary rank of Colonel.

Royal Army Medical Corps.

London Sanitary Company: Lieutenant A. M. Brown to be Captain. D. J. Peebles to be Lieutenant.

South Midland Casualty Clearing Station: Captain E. Whichells, from South Midland Field Ambulance, to be Captain.

South Wales Mounted Brigade Field Ambulance: J. O. Cuthbertson to be Lieutenant.

Northumbrian Field Ambulance: V. J. White to be Lieutenant.

Southern General Hospital: The undermentioned Majors to be Lieutenant-Colonels: W. Collier and R. H. A. Whitelocke. The undermentioned Captains to be Majors: E. C. Bevers, H. E. Counsell, J. C. R. Freeborn, A. G. Gibson, W. J. Turrell, and A. T. Waterhouse.

Attached to Units other than Medical Units.—Captain J. C. Denvir, from Yorks Mounted Brigade Field Ambulance, to be Captain. J. S. Hopwood to be Lieutenant.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

In the 96 English and Welsh towns with populations exceeding 50,000 persons at the last Census, 8486 births and 5868 deaths were registered during the week ended Saturday, April 8th. The annual rate of mortality in these towns, which in the three preceding weeks had been 18·7, 17·2, and 17·7 per 1000 of their aggregate civil population in 1915, was again 17·7 per 1000 in the week under notice. Among the several towns the death-rate ranged from 5·1 in Enfield, 7·5 in Southend-on-Sea, 7·7 in Ilford, 7·9 in Smethwick, and 9·1 in Willesden and in Tottenham, to 23·8 in Hull, 26·1 in Cambridge, 27·6 in Rochdale, 27·8 in Burnley, and 31·3 in Sunderland.

The 5868 deaths from all causes were 9 fewer than in the previous week, and included 381 which were referred to the principal epidemic diseases, against numbers rising from 345 to 420 in the four preceding weeks. Of these 381 deaths, 141 resulted from whooping-cough, 121 from measles, 50 from infantile diarrhœal diseases, 45 from diphtheria, 15 from scarlet fever, 8 from enteric fever, and 1 from small-pox. The annual death-rate from these diseases was equal to 1·1, or 0·2 per 1000 less than that recorded in the previous week. The deaths attributed to whooping-cough, which had been 93, 137, and 134 in the three preceding weeks, rose to 141, and caused the highest annual death-rates of 1·3 in Birmingham and in Manchester, 1·4 in Warrington and in Sunderland, 1·5 in Burnley, 1·9 in Cambridge, and 2·0 in York. The deaths referred to measles, which had been 127, 115, and 122 in the three preceding weeks, numbered 121 in the week under notice; the highest death-rates from this cause were 2·8 in Swansea, 3·9 in Newport (Mon.), and 7·5 in Rochdale. The fatal cases of diarrhœa and enteritis (among infants under 2 years), which had been 68, 65, and 66 in the three preceding weeks, fell to 50, and included 16 in London, 7 in Manchester, and 3 in Nottingham. The deaths attributed to diphtheria, which had been 61, 53, and 71 in the three preceding weeks, fell to 45, of which 12 occurred in London, 4 in Liverpool, and 3 each in West Ham, Bootle, and St. Helens. The deaths referred to scarlet fever, which had been 19, 12, and 20 in the three preceding weeks, fell to 15, and included 2 each in London, Stockport, and Leeds. The 8 deaths from enteric fever, of which 2 were registered in Hull, were slightly below the weekly average in the last quarter. The fatal case of small-pox belonged to South Shields.

The number of scarlet fever patients under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, which had steadily declined from 2257 to 1768 in the 11 preceding weeks, rose to 1778 on Saturday last; 252 new cases were admitted during the week, against 193, 210, and 214 in the three preceding weeks. These hospitals also contained on Saturday last 1425 cases of diphtheria, 243 of whooping-cough, 132 of measles, and 42 of enteric fever, but not one of small-pox. The 1481 deaths from all causes in London were 16 in excess of the number in the previous week, and corresponded to an annual death-rate of 17·9 per 1000 of the civil population. The deaths referred to diseases of the respiratory system, which had been 405, 337, and 328 in the three preceding weeks, further fell to 326 in the week under notice.

Of the 5868 deaths from all causes in the 96 towns, 194 resulted from violence, 458 were the subject of coroners' inquests, and 1673 occurred in public institutions. The causes of 60, or 1·0 per cent., of the total deaths were not certified either by a registered medical practitioner or by a coroner after inquest. All the causes of death were duly certified in Leeds, Bristol, West Ham, Bradford, Newcastle-on-Tyne, and in 69 other smaller towns. Of the 60 uncertified causes, 12 were registered in Liverpool, 11 in Birmingham, 5 in South Shields, 4 each in Gateshead and Tynemouth, and 3 each in London and Manchester.

HEALTH OF SCOTCH TOWNS.

In the 16 largest Scotch towns with an aggregate population estimated at 2,372,000 persons at the middle of last year, 1140 births and 890 deaths were registered during the week ended Saturday, April 1st. The annual rate of mortality in these towns, which had been 18·7, 20·7, and 19·9 per 1000 in the three preceding weeks, fell to 19·6 per 1000 in the week under notice. During the 13 weeks of last quarter the mean annual death-rate in these towns averaged 16·7, against a corresponding rate of 15·7 per 1000 in the large English towns. The death-rate during the week ranged from 6·2 in Ayr, 6·9 in Clydebank, and 12·0 in Hamilton, to 24·7 in Paisley, 25·2 in Kilmarnock, and 30·9 in Greenock.

The 890 deaths from all causes were 13 fewer than the number in the previous week, and included 93 which were referred to the principal epidemic diseases, against 89 and 82 in the two preceding weeks. Of these 96 deaths, 52 resulted from measles, 18 from infantile diarrhœal diseases, 8 each from diphtheria and whooping-cough, 7 from scarlet fever, and 3 from enteric fever, but not one from small-pox. The death-rate from these diseases was equal to 2·1, against 1·3 per 1000 in the large English towns. The deaths attributed to measles, which had increased from 23 to 43 in the four preceding weeks, further rose to 52, and comprised 30 in Glasgow, 6 in Kilmarnock, 4 each in Paisley and Coatbridge, 3 each in Edinburgh and Dundee, and 2 in Greenock. The deaths of infants (under 2 years) from diarrhœa and enteritis, which had been 8, 11, and 12 in the three preceding weeks, further rose to 18, and included 7 in Glasgow, 3 in Dundee, and 2 each in Paisley and Greenock. The fatal cases of diphtheria, which had been 7, 16, and 15 in the three preceding weeks, fell to 8, and included 2 each in Glasgow and Aberdeen. The 8 deaths from whooping-cough were 4 in excess of the average in the earlier weeks of the quarter, and comprised 3 in Glasgow, 2 each in Aberdeen and Paisley, and 1 in Kirkcaldy. The deaths referred to scarlet fever, which had been 6, 12, and 8 in the three preceding weeks, numbered 7, and included 2 each in Glasgow and Greenock. Of the 3 fatal cases of enteric fever, 2 were registered in Glasgow and 1 in Greenock.

The deaths referred to diseases of the respiratory system, which had steadily increased from 88 to 212 in the six preceding weeks, fell to 189 in the week under notice, but were 37 above the number registered in the corresponding week of last year. The deaths from violence numbered 24, against 26 and 29 in the two preceding weeks.

HEALTH OF IRISH TOWNS.

In the 19 town districts of Ireland with populations exceeding 10,000 persons at the last Census, 688 births and 572 deaths were registered during the week ended Saturday,

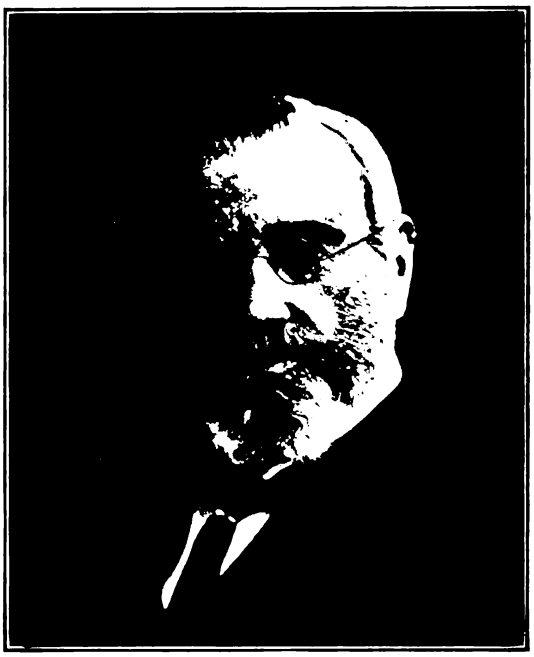
April 1st. The annual rate of mortality in these towns, which had been 24·5, 21·3, and 24·3 per 1000 in the three preceding weeks, rose in the week under notice to 26·0 per 1000 of their aggregate population, estimated at 1,148,468 persons at the middle of last year. During the 13 weeks of last quarter the mean annual death-rate in these towns averaged 20·6, against corresponding rates of 15·7 and 16·7 per 1000 in the English and Scotch towns respectively. During the week the death-rate was equal to 26·9 in Dublin (against 16·9 in London and 20·7 in Glasgow), 23·0 in Belfast, 33·3 in Cork, 20·2 in Londonderry, 32·5 in Limerick, and 20·9 in Waterford, while in the 13 smaller towns the mean rate was 28·4 per 1000.

The 572 deaths from all causes were 37 in excess of the number in the previous week, and included 47 which were referred to the principal epidemic diseases, against 38 and 45 in the two preceding weeks. Of these 47 deaths, 18 resulted from measles, 13 from whooping-cough, 8 from infantile diarrhœal diseases, 5 from diphtheria, 2 from scarlet fever, and 1 from enteric fever, but not one from small-pox. The death-rate from these diseases was equal to 2·1, against corresponding rates of 1·3 and 2·1 per 1000 in the English and Scotch towns respectively. The deaths attributed to measles, which had been 18, 16, and 18 in the three preceding weeks, were again 18 in the week under notice, and comprised 13 in Belfast, 4 in Dublin, and 1 in Londonderry. The deaths referred to whooping-cough, which had been 10, 8, and 15 in the three preceding weeks, fell to 13, of which 5 occurred in Dublin and 4 in Belfast. The fatal cases of diarrhœa and enteritis (among infants under 2 years), which had been 13, 10, and 5 in the three preceding weeks, rose to 8, and comprised 5 in Dublin, 2 in Belfast, and 1 in Clonmel. The 5 deaths attributed to diphtheria, of which 3 were registered in Belfast, were 2 in excess of the average in the earlier weeks of the quarter. The deaths from scarlet fever were recorded in Belfast and Cork, and that from enteric fever in Dublin.

The deaths referred to diseases of the respiratory system, which had been 124, 117, and 134 in the three preceding weeks, rose to 142 in the week under notice, and were 23 above the number registered in the corresponding week of last year. Of the 572 deaths from all causes, 171, or 30 per cent., occurred in public institutions, and 12 resulted from violence. The causes of 23, or 4·0 per cent., of the total deaths were not certified either by a registered medical practitioner or by a coroner after inquest, and included 7 in Limerick and 5 each in Dublin and Galway; in the large English towns the proportion of uncertified causes did not exceed 1·0 per cent.

In the 19 town districts of Ireland with populations exceeding 10,000 persons at the last Census, 515 births and 474 deaths were registered during the week ended Saturday, April 8th. The annual rate of mortality in these towns, which had been 21·3, 24·3, and 26·0 per 1000 in the three preceding weeks, declined to 21·5 per 1000 in the week under notice. The death-rate was equal to 22·6 in Dublin (against 17·9 in London and 21·7 in Glasgow), 19·1 in Belfast, 20·4 in Cork, 22·8 in Londonderry, 31·1 in Limerick, and 32·3 in Waterford, while in the 13 smaller towns the mean rate was 20·8 per 1000.

The 474 deaths from all causes were 98 fewer than in the previous week, and included 41 which were referred to the principal epidemic diseases, against 45 and 47 in the two preceding weeks. Of these 41 deaths, 16 resulted from whooping-cough, 13 from measles, 8 from infantile diarrhœal diseases, 2 from scarlet fever, and 1 each from enteric fever and diphtheria, but not one from small-pox. The death-rate from these diseases was equal to 1·9, against 1·1 per 1000 in the large English towns. The deaths attributed to whooping-cough, which had been 8, 15, and 13 in the three preceding weeks, rose to 16, and included 7 in Belfast, 3 in Limerick, and 2 each in Dublin and Cork. The deaths referred to measles, which had been 16, 18, and 18 in the three preceding weeks, fell to 13, and comprised 8 in Belfast, 4 in Dublin, and 1 in Newry. The fatal cases of diarrhœa and enteritis (among infants under 2 years), which had been 10, 5, and 8 in the three preceding weeks, were again 8 in the week under notice, and comprised 5 in Dublin, 2 in Belfast, and 1 in Londonderry. The deaths from scarlet fever were registered in Belfast and Cork, and that from enteric fever in Belfast, and the fatal case of diphtheria in Dublin.



The deaths referred to diseases of the respiratory system, which had been 117, 134, and 142 in the three preceding weeks, fell to 120 in the week under notice, and were 35 below the number registered in the corresponding week of last year. Of the 474 deaths from all causes, 155, or 33 per cent., occurred in public institutions, and 12 resulted from violence. The causes of 13, or 2·7 per cent., of the total deaths were not certified either by a registered medical practitioner or by a coroner after inquest, and included 5 in Dublin and 3 in Belfast, and 2 in Sligo; in the large English towns the proportion of uncertified causes did not exceed 1·0 per cent.

Obituary.

SIR THOMAS BOOR CROSBY, M.D. ST. AND., F.R.C.S. ENG., J.P., LL.D. ST. AND. & DUB.,

LATE LORD MAYOR OF LONDON.

WE regret to announce the death of Sir Thomas Boor Crosby, which took place on April 7th, after a brief illness, in his eighty-sixth year. Born at Gosperton, near Spalding, Lincolnshire, in 1830, the son of a farmer, he was educated in London, at University College School, and University College, and subsequently became a medical student at St. Thomas's Hospital. After obtaining the Licentiateship of the Society of Apothecaries of London and the Membership of the Royal College of Surgeons of England in 1852, having been demonstrator of anatomy in his medical school, he started in practice by joining an old-established firm of practitioners in Fenchurch-street. At that time the City of London was more of a residential quarter than it is to-day, and the firm to which he belonged had a busy practice among many leading City families. At a later period Dr. Crosby took up his residence in Finsbury, a recognised medical district less than 50 years ago. There he enjoyed a large practice, and there quite recently he described himself

SIR THOMAS BOOR CROSBY.

as being "still in harness." In 1860 he took the Fellowship of his College by examination, and in 1862 he graduated as Doctor of Medicine at the University of St. Andrews.

His connexion with municipal affairs dates back to 1877, in which year he was elected a Common Councillor of the City of London. He became Alderman for the Langbourne Ward, and 30 years later he served as Sheriff. During his year of office as Sheriff he paid, with other representatives of the Corporation, a visit to Berlin as the guest of the Berlin municipality, and in the same year he was knighted. In 1911, being the senior alderman below the chair, he was elected Lord Mayor of the City of London. He was then 82 years of age, and the choice of the City gave him the double distinction of being the first medical man to occupy the civic chair in the metropolis, and of being the oldest citizen who had ever undertaken the responsibilities of the Lord Mayor of London. In carrying out the duties of his office Sir Thomas Crosby was most conscientious and untiring, being ably assisted by his daughter as Lady Mayoress. During his mayoralty two events of outstanding importance occurred—namely, the appalling disaster to the *Titanic* and a coal strike which threatened to assume the dimensions of a national disaster. For the sufferers by the

foundering of the great White Star liner Sir Thomas Crosby raised £450,000 by a Mansion House Fund. When the coal strike was at a critical stage he convened a meeting of Lord Mayors, Mayors, and Provosts from all over the country at a few hours' notice, and the resulting intention on the part of the municipalities to take concerted action against impending danger did much to relieve the stress of a dangerous social situation. On retiring from the position of Lord Mayor the vote of thanks accorded to him in Common Hall was especially cordial, as it was recognised that he had used his civic position with great promptitude in the public cause.

In private life Sir Thomas Crosby was a shrewd, witty, kind, homely man, and his success was the outcome of persistent habits of hard work and self-restraint. He had no great learning, but he was an admirable magistrate, whose decisions were informed throughout with that real knowledge of the life of the people which the successful and industrious general practitioner cannot fail to possess. The distinctions bestowed upon him were many. He was an Officer of the Legion of Honour and possessed the Orders of the Crown (Germany), St. Olaf (Norway), Dannebrog (Denmark), and the Rising Sun (Japan). He was also LL.D. of Dublin and St. Andrews, a J.P. for the City of London as well as for the County of London, and a member of the Senate of London University.

TOM BATES, L.R.C.P. & S. EDIN., M.R.C.S. ENG.,

CONSULTING SURGEON TO THE WORCESTER GENERAL INFIRMARY.

Mr. Tom Bates, the well-known Worcester surgeon, died at his residence, Foregate-street, Worcester, after a brief illness on April 3rd, having just completed 50 years of medical practice.

Mr. Bates was a native of March, Cambridgeshire, and after studying medicine at Edinburgh, Glasgow, and Paris, took the Edinburgh double qualification in 1866, becoming a Member of the Royal College of Surgeons of England two years later. At the Glasgow Royal Infirmary he had the advantage of being a dresser to Lord Lister at a time when that distinguished surgeon was introducing the antiseptic methods of surgery a—fact which Mr. Bates recalled a few weeks ago in our columns, when he sent us for publication a letter which Lister had written to him in 1893 in reference to a case of tuberculous elbow. After acting as house surgeon at the Royal Infirmary, Glasgow, and holding other appointments at the Glasgow Lying-in Hospital and the Glasgow Lock Hospital, Bates went to Worcester, where he soon acquired a wide reputation as a surgeon and obtained a large practice in the neighbourhood. In 1879 he was appointed honorary surgeon to the Worcester General Infirmary, and worked assiduously for 30 years in the interests of that institution. Elected honorary consulting surgeon in 1909, he continued to work ungrudgingly for the infirmary, and two years ago, at the age of 70, and when he was on the eve of retiring into private life, he volunteered to act as resident house surgeon, the circumstances of the war having made it difficult to obtain house officers. His confrères in Worcester would not allow him to make the sacrifice, and the responsibility was shared among them. He was also keenly interested in the work of the Worcester Ophthalmic Hospital, to which hospital he was honorary surgeon for nearly 40 years. When the continuance of the war made the shortage of medical men severely felt, he again offered his services as resident in the infirmary, although he had by this time definitely retired from practice. Later he resumed active work when first one and then the other of the two sons who had taken his place in the practice accepted commissions in the Royal Army Medical Corps. He died, therefore, in the discharge of the duties that he loved and understood so well. In addition to the two sons, he leaves a widow and two daughters to mourn their loss.

He was buried at Astwood on April 7th, the coffin-plate being the name-plate from his house door bearing the simple words, "Mr. Bates, Surgeon."

THE LATE MARY CHARLOTTE MURDOCH.

WITH reference to the obituary of Miss M. C. Murdoch, which was published in THE LANCET of April 1st, a correspondent writes as follows:—"To those of us who knew Dr. Mary Murdoch intimately, to those who knew her as a great physician, or as a fearless reformer, a good public speaker and leader, or as a generous-hearted friend, it was not surprising that her passing was the occasion of a wonderful public tribute to her life and work. Thousands of the inhabitants of the city of Hull followed her to her last resting-place; friends and colleagues from many parts of England, representatives from many societies and associations and philanthropic institutions, as well as her townspeople, high and low, flocked to do her honour. Her life and work in the practice of her profession has for many years past been an inspiration to many. She had that extraordinary love of little children which one often finds in very strong characters. It was an education in itself to do the hospital 'round' with her and see the real delight of the little patients and the greeting they gave her when she came into the ward, the sound clinical work, the instruction to her house surgeons, and the amount of original work done; for she did some valuable scientific research, more especially in the field of pericarditis, and the vaccine treatment of many diseases. She was essentially a clinician of the first water, a good diagnostician, with a remarkable power of pulling her patient round again. Her life was a life of devotion and utter self-sacrifice. As a doctor she knew no rest. Nothing was a trouble to her where her patient was concerned, and she had a wonderful way of cheering and bestowing comfort and bringing gladness wherever she went. Her loyalty towards her colleagues, her generous help to those in trouble or want, her radiant personality, her spirit of adventure, and her championship of all righteous causes will make her live in the memory of many as a great physician who will be greatly missed."

Correspondence.

"Audi alteram partem."

THE PREVENTION OF BILHARZIA INFECTION.

To the Editor of THE LANCET.

SIR,—There are several means of preventing the spread of bilharziosis amongst civilians, and more especially amongst troops now on active service. Up till recently, South African practitioners advised persons to avoid swimming in those rivers and pools which were known to be associated with the disease. The filtering of the town supply of fresh water has been attended with a marked diminution of the number of cases of bilharziosis in some towns; but the removal of the intermediary hosts from places where they are exposed to infection or are likely to cause infection has not received the attention it deserves. There is a significant distribution of one form of fresh-water snail in Natal. This snail could well be removed from certain parts of the country where bathing is indulged in. So far we have no reason to suppose that these snails are a danger to the community until they have come into contact with urine passed by a person suffering from bilharziosis. There is reason to suppose that infected persons such as coolies and others may infect a river at its source, that these snails which abound on the rushes lower down stream become a source of danger to the water-supply within a month or six weeks, and that healthy persons who make use of this river water for drinking or bathing purposes during the next day or two are liable to contract the disease.

Certain snails have been proved to act as intermediary hosts for Asiatic schistosomiasis in China and Japan. The Bilharzia Mission to Egypt in 1914 demonstrated that several varieties of fresh-water snails could act as intermediary hosts for the Egyptian form of the disease. I have found a dark sinistral snail, Physopsis africana, abounding in several of the bathing-places in Natal which are known to be associated with bilharzia infection. These snails were particularly abundant in three places where the infection is believed to be particularly severe. This common fresh-water snail has been found to harbour two different species of cercariæ presenting forked tails here in Natal. From this I infer that this species of snail may act as an intermediary host for bilharziosis in South Africa.

I am, Sir, yours faithfully,

F. G. CAWSTON, M.B., B.C. Cantab.

Maritzburg, Natal, March 3rd, 1916.

THE OPERATIVE TREATMENT OF OSTEO-ARTHRITIS.

To the Editor of THE LANCET.

SIR,—While fully appreciating the complimentary references to my operative work in connexion with cases of osteo-arthritis, my attention has been drawn to an injustice to Mr. Sampson Handley which your annotation in THE LANCET of April 1st inadvertently suggests. My case, to which you so kindly refer, was admittedly the first of the kind, but Mr. Handley, working independently, was the first to publish his results, and he also was responsible for the term "cheilotomy." Mr. Handley published his operative experiences on this subject in the *British Medical Journal* of May 3rd, 1913. My case, although operated upon three months before Mr. Handley's first case, was not published until a week later (May 10th) in the same journal.

I intend to send you a further communication with X ray photographs illustrating the operative procedures required in the treatment of osteo-arthritis, and will then be able, if you will kindly permit me, to fill in the gaps to which THE LANCET refers.—I am, Sir, yours faithfully,

Dublin, April 7th, 1916. W. I. DE C. WHEELER.

ANÆSTHESIA FOR ENUCLEATION OF TONSILS.

To the Editor of THE LANCET.

SIR,—In THE LANCET of April 8th Dr. J. Blomfield advocates the use of ether for the above operation. No doubt in the hands of a general practitioner it is the safest anæsthetic, but the results, to my mind, are not to be compared with those obtained by the use of chloroform and oxygen. Addition of the latter lessens the risk, and I have used this combination in over 1000 cases successfully. All patients over the age of 16 have a preliminary hypodermic injection of morphine and atropine. Anæsthesia is induced very gradually with chloroform dropped on to a mask with one layer of flannel; as soon as the patient is just under, a mouth prop is fixed in position and warmed oxygen is passed through chloroform and thence to a pipe fixed to the mouth prop This usually suffices to keep the patient under with no faucial straining for half an hour or more, though occasionally it is necessary to use the mask for a few minutes after the removal of one tonsil. The advantages over ether are: no congestion, less tendency to vomiting, more agreeable odour, and the patient comes round rapidly. It is easy with practice to keep the patient in the ideal stage—that is, deep enough to avoid faucial straining and light enough to enable the cough reflex to be recovered in a few seconds.

I am, Sir, yours faithfully,

HUGH R. PHILLIPS, M.D. Edin.,
Senior Anæsthetist, Italian Hospital, &c.

Dawson-place, W., April 9th, 1916.

THE DROITWICH BRINE BATHS.

To the Editor of THE LANCET.

SIR,—In consequence of the large number of soldier patients who are receiving free treatment at the brine baths at Droitwich an impression appears to be entertained by certain medical men that the baths have, for the time being, been given over entirely to military patients.

Such is not the case, and the arrangements for dealing with ordinary cases are in nowise affected.

I am, Sir, yours faithfully,

J. H. HOLLYER,
Director of the Brine Baths.

Droitwich, April 7th, 1916.

ENTERIC AND TYPHOID: A POINT IN NOMENCLATURE.

To the Editor of THE LANCET.

SIR,—Since the differentiation of the typhoid group of disease into the three varieties caused by the Eberth-Gaffky bacillus, the B. paratyphosus A, and the B. paratyphosus B respectively, a need has arisen for one word which can be used for the whole group in common. In the large majority of cases it is quite impossible to diagnose clinically the three infections one from the other; and it is not always possible to obtain readily bacteriological aid.

There is no necessity, however, to coin another word, as we possess two already which are used interchangeably—"typhoid" and "enteric." I suggest that the word "enteric" be used to denote all or any of the three infections above mentioned, and any similar that may hereafter be differentiated; and that the word "typhoid" be restricted to cases of infection by the Eberth-Gaffky bacillus.

I am, Sir, yours faithfully,

E. W. GOODALL.

Eastern Hospital, Homerton, N.E., April 10th, 1916.

STEEL HELMETS FOR THE ARMY.

To the Editor of THE LANCET.

SIR,—Although no one can approve of the manner in which an officer of the Royal Army Medical Corps drew attention recently in the House of Commons to the need for the issue of steel helmets to the army, yet every surgeon who has seen much of the wounds received by our soldiers in the present war will agree that there is a most pressing need for the supply of steel helmets to the soldiers. No small proportion of the wounds received involve the head, and the use of a steel helmet would have prevented very many of these. Even when the bullet or shell fragment has done no more than groove the scalp, a convalescence of several weeks is required before the soldier can return to the firing line, and if we put the matter on the low level of expense, it is clear that much money is unnecessarily used in the carrying of these soldiers to and fro. The skull itself is, however, in many cases grooved, and in these cases the throwing off of the necrosed portion of bone will take many weeks. In other cases still the brain has been injured, and in a large proportion of these a fatal result has followed. It is often said that a steel helmet cannot be devised which is capable of preventing all bullet wounds of the cranium. This is no doubt true, but it is equally true that a very large proportion of the projectiles would be arrested. The Government has already issued a few hundred thousand steel helmets, but the delay in issuing the remainder is entirely unnecessary, and I cannot doubt that if the authorities appreciated the value of the steel helmet very little time would elapse before all our troops serving at the front would be provided with it.

I am, Sir, yours faithfully,

April 8th, 1916. F.R.C.S.

DIFFERENT NAMES FOR IDENTICAL SUBSTANCES.

To the Editor of THE LANCET.

SIR,—With regard to the annotation in your issue of April 8th relative to the use of the word "Tolamine" as a short title for para-toluene-sodium-sulphochloramide, we suggested the use of this word to the authors of the research in place of chloramine or chloramine-T, the names they gave to the substance, because the word chloramine has been used by John Wyeth and Brother, Philadelphia, for at least 25 years to denote a compound chloride of ammonium pastille manufactured by them.

We were desirous of respecting the wishes of the investigators by adopting the title they suggested, but felt bound to regard the vested interests of the manufacturers who had used the word chloramine for at least a quarter of a century to describe a particular preparation of their manufacture. We made our position in the matter perfectly clear to the investigators and gave them the option of adopting "Tolamine" as a common word for the substance, but as they did not agree to this suggestion we then explained that it was impracticable for us, in the circumstances we had mentioned, to use the word chloramine or chloramine-T (the latter title still containing the word chloramine), and we should therefore issue the preparation under the word "Tolamine" and register it as our trade mark.

In our opinion the use of the word chloramine involves the danger of using one name for many substances, as, quite apart from the confusion which will arise with the existing proprietary preparation, chloramin and chloroamine are applied to the simple compound NH_2Cl, and further there is additional risk of confusion with the Codex preparation chloramide. From the trade point of view the *Chemist and Druggist* has also pointed out that there is likely to be a good deal of confusion in the use of the word chloramine proposed for para-toluene-sodium-sulpho-chloramide.

We are, Sir, yours faithfully,

BURROUGHS WELLCOME AND CO.

Snow Hill Buildings, E.C., April 10th, 1916.

The War.

THE CASUALTY LIST.

THE following names of medical officers appear among the casualties announced since our last issue :—

Killed in Action.

Major W. L. Hawksley, R.A.M.C. (T.F.), qualified in 1904, and held a public health appointment at Liverpool prior to the war.

Died.

Captain F. F. German, R.A.M.C., qualified in 1881, was in charge of the Military Hospital at Seaforth Barracks, and was medical officer of health for Waterloo with Seaforth, Liverpool.

Colonel A. E. J. Barker, A.M.S. (Major 3rd London General Hospital, R.A.M.C.) was educated at Dublin and at Bonn University, and was Professor of Surgery at University College, London.

Major R. S. Smyth, R.A.M.C., received his medical education at Dublin, qualifying in 1904, and joined the R.A.M.C. in 1905. He was mentioned in despatches by Viscount French, and was a well-known football player in Ireland.

Captain G. F. Barr, R.A.M.C., qualified in 1914 at Glasgow, and joined the R.A.M.C. in January, 1915.

Wounded.

Captain C. R. Woodruff, R.A.M.C.

Lieutenant N. McCall-Smith, R.A.M.C.

DEATHS AMONG THE SONS OF MEDICAL MEN.

The following sons of medical men must be added to our lists of those who have fallen during the war :—

Colonel A. E. J. Barker, A.M.S., son of the late Dr. W. Barker, of Dublin.

Major W. L. Hawksley, R.A.M.C., son of the late Dr. H. L. Hawksley, of Southport.

Lieutenant J. Nichol, Royal Scots Fusiliers, and Flying Officer, Royal Flying Corps, second son of Dr. F. E. Nichol, of Margate.

Second Lieutenant C. B. Underhill, West Yorkshire Regiment, fourth son of Dr. F. T. Underhill, formerly of Tipton, Staffs., and now medical officer of health of Vancouver City, British Columbia.

MENTIONED IN DESPATCHES.

In a despatch to the Chief of the General Staff, Army Headquarters, India, dated Jan. 1st, 1916, dealing with the operations in Mesopotamia, General Sir John Nixon, K.C.B., mentions the following medical officers for distinguished service :—

Surg.-Gen. H. G. Hathaway, C.B.
Col J. F. D. negan, R.A.M.C.
Col. P. Behir, I. M.S.
Col. H M. Adamson, R.A.M.C.
Lt.-Col. E. Jennings, I.M.S.
Lt.-Col. H. O. B. Brown-Mason, R.A.M.C.
Maj H R. Brown, I.M.S.
Maj. A. Spitteler. I.M.S.
Maj. S. Anderson. I.M.S.
Maj. F. C. Lambert, R.A.M.C.
Capt. G. Wilson, R.A.M.C.
Capt. P. B Bharucha, I.M.S.
Capt. R. O. Clifford, I.M.S.
Capt. R. E. Flowerdew, I. M.S.
Capt. F. A. Robinson, R.A.M.C.
Capt K K. Mukerji, I.M.S.
Capt. J Stirtin, R.A.M.C.
Lt. R. V. Martin, I M.S.
Lt F. T. Simpson, R.A.M.C.
2nd Class Asst.-Surg. E. S. Shede
3rd Class Asst.-Surg. H. A. Cotton

MILITARY ORTHOPÆDICS.

Lieutenant-Colonel Robert Jones, R.A.M.C. (T.), has been appointed by the War Office Inspector of Military Orthopædics, and military hospitals will be organised and conducted under his supervision specially to deal with the injuries to limbs and joints of men wounded in the war, with the object of fitting them for civilian employment. The support and practical assistance of the British Red Cross have been secured for a scheme which those who have witnessed at the Roehampton Hospital what can be done in these directions know will have a valuable outcome.

MEDICAL NOTES FROM THE SALONICA FORCE.

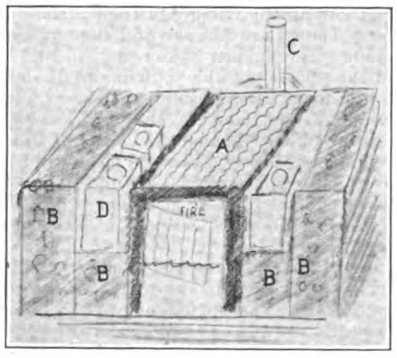
A Field Ambulance Officer with the Salonica Force writes as follows:—Everyone is aware of the somewhat unique position of the Allies' army around Salonica. The medical arrangements of the Salonica Force, after the retreat, have been carried out under conditions somewhat easier than those in a country where it has been necessary to plan and erect hospitals at the time when heavy fighting has already commenced. The outstanding feature of medical interest while British troops were in the Lake Doiran district was the amount of frost-bite—true frost-bite—not the "frozen feet" of France in the winter of 1914–15. At the present time the lines of communication are not long, but the similar medical units exist as in France—field ambulances, casualty clearing stations, stationary and general hospitals. The railroads and roads are few, and so transport of sick and wounded forms one of the difficulties of the medical service. The methods adopted to overcome these difficulties and the sanitation of the camps are the interesting topics to the medical man.

The present tactics have made it possible to have all the hospitals and casualty clearing stations on good roads, and motor transport is available between these and the quay. In France motor ambulances were able to work with the field ambulances; in Greece that is not at present possible owing to the few roads in existence. The method of transport available will be mentioned later. The general hospitals are under canvas and have been able to find good sites owing to the extent of open plain which exists on two sides of the town for some distance.

The hospitals are occupied with treating the average influx of sick from the army. There is no outstanding disease, although a type of fever not simulating any text-book fever has been prevalent. It is of a relapsing type—hence comparable to "trench fever." It occurs in men of every age and commences suddenly with pyrexia of about 100° F., the pulse-rate rising correspondingly. The pyrexia lasts 48 hours as a rule, and then an apyrexia period follows, lasting three, four, or five days; some observers state as long as seven days. Then a pyrexial period recurs lasting 48 hours. Cases are established with three and four relapses. Symptoms are not plentiful and often limited to back pains and pains in the legs, particularly down the shins. No physical signs of anything abnormal in the circulatory, respiratory, and alimentary systems exist; a few observers record some cases with diarrhœa, but this is the exception. The noticeable feature is the persistence of pains during the apyrexial period. There are no cases recorded of important complications, but patients require a considerable time to convalesce after several relapses of fever. Pathologists have shed no light on the origin of the disease at present. The population of the town suffer from malaria, and this occurs in all the villages of the district. It appears that the worst months are August and September. Cholera occurs in epidemics, the last two being in 1911 and 1913. All the medical officers are able to acquaint themselves with a knowledge of local diseases and conditions, owing to the early formation of the Salonica Medical Society, of which Surgeon-General W. G. Macpherson, C.B., is the president. This society meets weekly at each hospital in turn, and discussions and demonstrations lasting about two hours are eagerly attended. The proceedings will be published from time to time in the *Journal of the Royal Army Medical Corps*.

The success of the sanitary arrangements will be tested when hotter weather commences and flies begin to breed, but the details of these as carried out by the Salonica force are of interest, as are also the means of transport from the regiments and ambulances to the clearing stations, and with the aid of the few sketches here reproduced these will be described.

Sanitation.



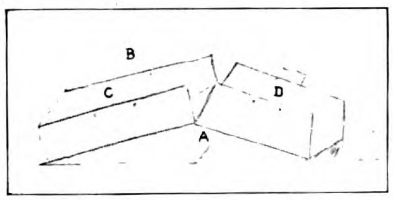
The country around Salonica occupied by the army consists of a range of hills, in most places about 1000 feet above sea-level, with plain on each side of the range. These hills are broken up by many gorges, in each of which runs a stream after any fall of rain, and in the larger valleys always one finds a stream rushing down. The larger streams at this time of year increase to double their size after 12 hours of steady rain. The country therefore possesses one outstanding advantage for camping sites—plenty of streams, and hence

a persistent water-supply at this time of year. On the other hand, the tendency for the water to stand on much of the level ground makes every camp wet unless properly drained.

It has been somewhat easier to carry out sanitary arrangements in the Salonica army than in some fighting zones, for there has been no fighting in the present position. Regimental sanitation has not been difficult, for in most cases the regiments have been divided up, and a camp of under 500 men with few horses and mules is not difficult to keep clean. In regard to the water, this is brought from the stream on mules, each mule carrying a metal urn covered with cloth on each side of the pack saddle, or a "pakkal," which consists of a rubber bag inside a canvas valise. From these the water is poured into zinc tubs, each provided with a lid. In these tubs is placed chloride of lime to purify the water. The water, however, is extraordinarily pure. Most of the streams that have been tested have proved to be of excellent water. In fact, one gathers that the only water-supply that has been polluted at any time was one near the base; in this case a pipe came from the stream to large storage tanks near a road, and from the tanks the water was drawn for surrounding units. The water is clear, and so clarification is not required except after a heavy storm, such as causes the streams to bring down mud with the water. In some places the purification of the water does not rest with the unit, as is usually the custom, but the divisional sanitary officer employs some of his orderlies to carry out the necessary purification of the water at the edge of the stream or beside the spring from which the water is drawn. This system has obvious advantages, and is carried out by having a series of zinc tubs beside the supply. These are kept full and the requisite quantity of chloride of lime added from time to time. By this method disease due to water contamination is unlikely to occur, but of course would affect a large number of men. A source of water which has not been mentioned is the ancient aqueduct. This sounds perhaps fabulous, yet several fine aqueducts still exist and show signs of modern workmanship. Each has a cross-section of about one square foot and is walled and roofed by good cement. The water is excellent, both clear and free from all salts and organisms. It flows uphill in places and forms part of the water-supply to the town. There is no chance of pollution of these aqueducts except at the small openings from which water is drawn. What quantity of water will be available from these natural sources in the hotter weather cannot be foretold.

The disposal of all forms of refuse and excreta is a subject on which much has been written, and so many methods are adopted, each of which fulfils the same purpose. From experience in France most units adopt the method of burning

FIG. 1.



Incinerator showing method of heating water. A, Roof; B, mud walls C, chimney; D, biscuit-tin containing water. Size, 6 ft. square; incinerator, 6 ft. by 3 ft. by 2 ft.

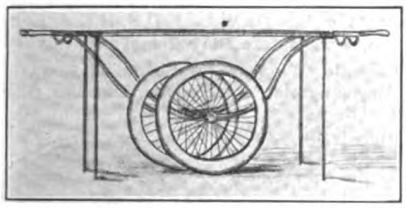
all solid refuse, and treating all liquids so that they will be absorbed by the earth from pits. Dealing first with solids, one finds that horse and mule dung predominates over all other refuse in the majority of units, as it is necessary to have mules for transport. This is dealt with by incineration, thus preventing any accumulation of manure. The incinerator used in most units is about 4 feet square and 4 feet high, and if one is insufficient several are built out of mud and stones. A new type is in use in some places consisting of a central support such as a biscuit tin and radiating iron strips fixed on pieces of wood protruding 18 inches from the ground. The iron strips are the bands fixing the fodder together, and about a dozen are required for the incinerator. The manure is thrown on to this and burns well, as it is raised off the ground and has a free draught from below. An ingenious incinerator has been devised, which serves a double purpose, the second one being to heat water for washing purposes. This is done by building with mud and stones round the incinerator an additional wall. It is only possible in a square or rectangular incinerator. Between the two walls the floor is raised with more mud, and on this are placed biscuit tins with water in them. It is found that when an incinerator is burning well the water is quickly heated, and six or eight tins of two gallons' capacity can be heated at the same time. (Fig. 1.)

Human excreta are dealt with in a similar manner to manure—i.e., incineration. Surgeon-General Macpherson takes a great interest in latrine systems, and while Director of Medical Services to the First Army in France he introduced a system of latrine, which became popular where it was in use. This type of latrine has become much more general in the units of the Salonica army, and is seen at its best at the New Zealand Stationary Hospital. Full details of the latrine were published last January in the *Journal of the Royal Army Medical Corps*. There are two tins (see Fig. 2), each consisting of half of a Pratt's petrol tin. Each

FIG. 2.

Macpherson latrine system. Two half-tins in position. A, End of tin (everted to raise end); B, handle of wire; C, for urine; D, for fæces.

tin is placed on the ground with one end raised 4 inches, the two raised portions being together. A man squatting over these tins defæcates into one and urinates into the other. That is not all. A piece of newspaper, about 12 inches by 18 inches, is placed in the hindmost tin, and the stool is passed on to this; when the man has completed his defæcation it is then his duty to remove his own excreta from these tins. The front tin is emptied into a drain leading into a pit, so that the urine is absorbed by the earth. The newspaper is taken with the stool inside it and placed on a special incinerator. The tins are replaced in position, and a piece of paper laid on to the hindmost tin so as to be ready for the next man. The incinerator is kept in most hospitals for dealing with fæces alone. It is found that fæces burn well with an odour to which all grow accustomed, and it has been likened to that of a bad Turkish cigarette. Some prefer to dry the fæces at the side of the tin in which they are burning. Any quantity can be dealt with by this method. The advantage of burning fæces is obvious, and the simple method of separating fæces and urine facilitates their destruction by burning. Strict discipline is necessary for this latrine system to be worked, so that tins are never soiled. After a lecture and posting of rules how to use these latrines it has been found that they work excellently, especially if an orderly or convalescent patient is employed at the latrine to supervise the adherence to the rules. The advantages of the system are manifest when one realises that flies have no place to lay eggs in any fæcal matter, for only a minute elapses between the passing of the stool and its disposal in the incinerator. Some units separate fæces and urine by two tins under a seat, as a rule consisting of a V-shaped piece of wood placed on three uprights, the point of the V being in front. Prevention of breeding of flies is the object of all, and the chief point aimed at is the incineration of all solid matter.



A matter of sanitary interest in this area is that during December and January whenever a unit went to a new camp site it was almost invariably necessary for them to remove carcasses from the ground. The Greek has a habit of driving a bullock, mule, pony, or donkey until the beast actually falls down dead. He then leaves the beast beside the road. Later he appears and removes the hide, leaving the carcass

on the spot. From the number of these carcasses one would imagine the mortality of the beasts of burden is high. The vultures attack the carcasses, and a most insanitary state of affairs exists until dealt with by our sanitary officers.

Transport.

As the tactics differ in trench warfare and fighting in mountainous country, so likewise the medical arrangements *in toto* suitable in France would be unsuitable for any army fighting around Salonica or in Bulgaria or in Serbia. Thus

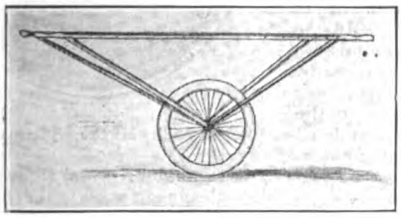


FIG. 3.

Miller-James collapsible stretcher carrier.

changes in the equipment and transport of field medical units of the Salonica force have been made to make units previously in the Dardanelles or France efficient to deal with sick and wounded in a country with geographical conditions differing from those which such units have formerly experienced. In France trench stretchers and motor ambulances were necessary accessories to the original equipment, but in the Near

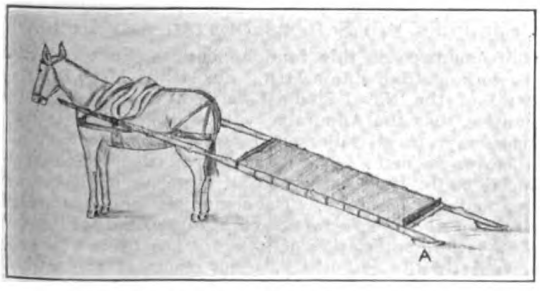

FIG. 4

Mono-wheel stretcher carrier.

East improvisation of stretchers and modes of transport are necessary, as roads are few and hill tracks are all that can be depended on as a route for casualties from field units. Hence one finds the motor ambulance confined to a small area close to the sea. Horse ambulances (Mark VI. and Mark I.) can go further; the former is heavy, weighing $1\frac{1}{4}$ tons, and in winter sinks deeply into the mud; the latter is light and well sprung, and weighs $\frac{3}{4}$ ton, and is suitable for good hill tracks.

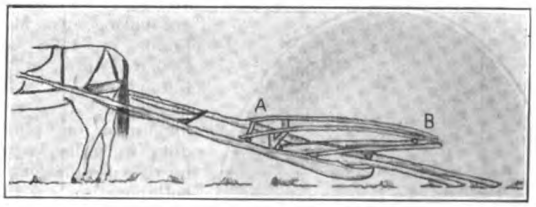

FIG. 5.

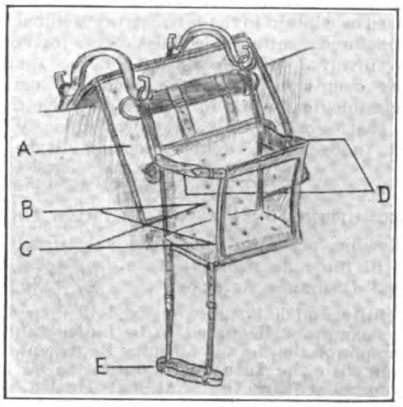
Simple travois (after Greenleaf). A, Shoe.

Wheel stretchers are being modified that mules can pull them up tracks. In some cases shafts are fixed to these, and in others the traces are fixed to swingle-trees attached to the carriage. Three forms of wheel stretcher exist—the army type, the carriage, ambulance-stretcher, Mark I., which has large wheels; the Miller-James folding carriage, consisting of two motor-bicycle wheels and metal framework (Fig. 3), and a mono-wheel introduced during the last year, which consists of one motor-bicycle wheel and light folding framework. (Fig. 4). Travois are being made by units, and many different kinds were displayed at an exhibition in January. Some were cumbersome and others would not stand the trial given to them over a piece of rough ground. The essential requirements are that a wounded man may be able to lie on a stretcher (or improvised substitute) and be pulled by a mule with as little shaking as possible, the whole vehicle being able to get over ditches and rough ground. To suit these conditions it is found that the travois made out of green wood takes the first place. The simple travois, after the style of Greenleaf's travois (Fig. 5), is not a great success, but the shock of going over rough ground is diminished 50 per cent. by making one leg of the travois 1 foot to 8 inches shorter than its fellow. Another method of obviating this difficulty is to have a third and larger leg in

FIG. 6.



Harris travois. Patient lies between A and B on sack filled with leaves.

the centre, which only comes into use on uneven ground and diminishes the shaking of the patient greatly. (Fig. 6.) Manufacture of these conveyances is facilitated by the quantity of wood in many of the places which ambulances have chosen for their dressing stations.

Mule transport for patients is useful for such as need not travel lying down. A strong mule is required to carry two patients sitting in cacolets, one patient on each side of the pack-saddle. (Fig. 7.) This is not an uncomfortable chair,

FIG. 7.

A, Pack-saddle; B, leather cushion; C, collapsible iron frame D, strap; E, foot support.

and the stronger mules work readily if the weight is equally balanced. Litters have been made to fix to the pack-saddles, one litter each side of a mule or two between two mules. Stretchers are not adaptable for fixing on to mules for transport of lying-down cases. It is more than probable that the lying-down case will experience great hardship as he is evacuated.

To sum up the available transport:—I. In any locality: (1) hand-carriage—(*a*) on army stretcher (Mark II.), (*b*) on trench stretcher in which patient's back is supported against the back of the front bearer; (2) wheel-stretcher—(*a*) mono-wheel, (*b*) two-wheeled, either may be pulled by a mule; (3) travois; and (4) litters. II. Where tracks exist: Horse or mule ambulances—(*a*) heavy, and (*b*) light. III. Where roads exist: Motor ambulances.

OBITUARY OF THE WAR.

JOHN TEMPLE LEON, M.D., B.Sc. LOND., M.R.C.S., L.R.C.P. LOND., D.P.H. CAMB.,

CAPTAIN, ROYAL ARMY MEDICAL CORPS (T.).

Captain John Temple Leon, who died at Southsea on March 30th from cerebro-spinal meningitis, contracted from a military patient under his care, was 50 years of age. He started with the intention of being a scientific chemist, and after leaving Clifton went to Germany. Subsequently he entered at University College, London, where he was Tufnell scholar in 1885. Two years later he graduated as B.Sc. Lond., and in 1890 was appointed assistant lecturer on physics and demonstrator of chemistry in St. Mary's Hospital Medical School. After holding those appointments for three years he commenced his medical studies at St. Mary's, where he had a successful career, graduating as M.B. Lond. in 1896 and D.P.H. Camb. in the following year. After qualifying he was appointed on plague duty in India, where he did useful work in collaboration with Professor Haffkine. Subsequently he served throughout the South African War and was for the greater part of the time attached to No. 8 General Hospital at Bloemfontein. On his return from South Africa he was for a time assistant medical superintendent of Paddington Infirmary, after which he settled in practice at Southsea and was shortly afterwards appointed honorary assistant physician to the Royal Portsmouth and Gosport Hospital. On the outbreak of the present war he was mobilised as captain in the Royal Army Medical Corps (T.) and was appointed sanitary specialist officer for Portsmouth. His duties involved the inspection of the sanitation of the various camps in Hampshire, and the carrying out of the bacteriological work in connexion with the various epidemics that arose. He worked assiduously at these posts, and there is no doubt that his death was due to his unsparing devotion to duty. He had for several weeks been thoroughly overworked, and proved susceptible to infection from a severe case of cerebro-spinal meningitis. He first showed the symptoms of the disease on March 20th. It rapidly acquired a virulent form, and in spite of the devoted attention that he received from his colleagues, Lieutenant-Colonel C. F. Routh and Major C. A. S. Ridout, he died ten days later. He leaves behind him the record of a brave man who worked unsparingly for his country, whilst the medical profession in Hampshire is the poorer for an excellent physician and an able bacteriologist.

RONALD WINGRAVE DUNCAN, L.R.C.P., L.R.C.S. EDIN., L.F.P.S. GLASG., L.D.S. R.C.S. EDIN.,

CAPTAIN, ROYAL ARMY MEDICAL CORPS.

Captain Ronald Wingrave Duncan, who was killed in action in Mesopotamia, at the age of 33, received his medical and dental education in Edinburgh. After qualifying in 1906 he held appointments at the West Bromwich District Hospital; Salford Royal Hospital; Norfolk and Norwich Hospital; David Lewis Epileptic Colony, Alderley Edge; Monsall Fever Hospital, Manchester; and Ladywell Sanatorium, Salford. He left the last appointment in November, 1914, to take a commission in the Royal Army Medical Corps. He was attached to the 2nd Black Watch, Bareilly Brigade, Meerut Division, Indian Expeditionary Force.

Dr. James Fletcher writes of him: "Mr. Duncan was a most pleasant and capable colleague to work with, and though naturally of a very retiring disposition he was a thorough sportsman, with a keen sense of humour, which found its full vent when in congenial company. His extremely kindly disposition and sympathy for others endeared him to his patients and the staff, and I shall always have the happiest recollections of my association with him."

THE RECRUITING OF PHARMACEUTICAL CHEMISTS.

The following provision has been substituted for that previously in force as regards chemists dispensing under the National Insurance Acts:—

Men lawfully and habitually engaged in dispening medicines to be exempted if agreed to be indispensable for the needs of the population by the Military Representative, after consultation with the Insurance Committee for the area,* or if recommended by the National Health Insurance Commission and approved by the Army Council.

* The Insurance Committee shall consult the Pharmaceutical Committee before deciding which cases to recommend for exemption.

This provision places the Insurance Committee for the area in a position of responsibility as regards the dispensing service of the whole of the civil population, and not solely as regards the dispensing service of insured persons; but the National Health Insurance Commission points out that the proper consideration of the insured must necessarily involve attention to the needs of the civil population as a whole, since it is doubtful whether in any circumstances the requirements of insured persons could be adequately served unless the available chemists were in a position to cope simultaneously with the needs of the uninsured. The Insurance Committees are therefore enjoined to consult with the Pharmaceutical Committee as to the list of persons to be recommended to the Military Representative for exemption, and in the event of any disagreement between the Insurance Committee and the Military Representative as to the exemption of any of the persons whom the Committee, after consultation with the Pharmaceutical Committee, consider to be indispensable, the question can be referred to the Commissioners.

SOLDIERS AND SAILORS DENTAL AID FUND.

The committee of this fund announces the termination of its work, as from March 11th. Sir Arthur May, Director-General of the Naval Medical Service, has informed the committee that the Admiralty will supply artificial teeth, if necessary, to all sailors and recruits for the navy and all the overseas men. The War Office has decided to supply artificial teeth, if necessary, to all overseas men, but not to the home-service army. The committee can congratulate itself upon the success of its efforts on behalf of the two services; the appreciation of its work has been constantly expressed by the authorities. The report of the work of the committee shows that since its inception the fund has dealt with over 11,000 fighting men, and this without paying salaries, rent, rates, or taxes. Owing to the patriotism of the press and the generosity of the supporters of the fund no expenses have been incurred in advertising. Since November, 1915, the committee has paid for all the artificial teeth of the home-service men.

AMONG the new justices of the peace for the County of London is Mr. Morgan I. Finucane, surgeon and barrister, of Ashley-place, S.W.

Medical News.

UNIVERSITY OF OXFORD.—The following degree has been conferred:—

Doctor of Medicine—Alfred Leslie Pearce Gould, Chr. Church.

EXAMINING BOARD IN ENGLAND BY THE ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—At the Second Professional Examination in Anatomy and Physiolology held on March 30th and 31st, and April 3rd and 4th, 78 candidates presented themselves, of whom 56 were approved and 22 were rejected. The following are the names and medical schools of the successful candidates:—

Yenny Abdel-Messiah, King's College; Abraham Abelson and Norman Dyer Ball, University College; Margarita Sargood Barfield, London School of Medicine for Women; Jules Samuel Boruchowitz, Brussels University and University College; Jean Auguste Andre Bouic, Guy's Hospital; Osmond Hayman Brown, Charing Cross Hospital and King's College; Norman Carwardine Cooper, Bristol University; Andrew Norman Macdonald Davidson and Evan Sherrah Davies, King's College; Frank Swinburne Drewe, St. Thomas's Hospital; Abraham Eldinow, London Hospital; Frederick Knowles Escritt, Guy's Hospital; Frederick Augustus Evans, London Hospital; Paul Faraci, Beirut and King's College; John Eskdale Fishburn, Guy's Hospital; James O'Farrell Fletcher, St. Mary's Hospital; Richard Gainsborough, Oxford University; Edwin Stowell Gawne, Liverpool University; Nannie Gibson, London School of Medicine for Women; Chapple Gill-Carey, Guy's Hospital; Philip Eldon Gorst, Liverpool University; Lawrence Handy, St. Bartholomew's Hospital; Herbert William Hill and Tom Robert Ernest Hillier, Middlesex Hospital; Anthony Bancroft Isaacs, St. Thomas's Hospital; George Henry Johnson, Middlesex Hospital; Ernest Francis Kerby, Guy's Hospital; Haji Hyderali Khan, Bombay University and Guy's Hospital; Francis Wharton Lemarchand, St. Bartholomew's Hospital; Pierce Lloyd-Williams, Douglas McClean, and John Joseph Myles MacDonnell, St. Thomas's Hospital; Charles Moffatt, Guy's Hospital; John Stephen Moore, St. Thomas's Hospital; Arthur Richard Neckles, Guy's Hospital; Clement Nicory, St. Thomas's Hospital; Arthur Gordon Ord, Guy's Hospital; Leonard Duncan Porteous, St. Bartholomew's Hospital; Percival George Quinton and Walter Ernest Quitman, University College; David Hesketh Richards and Enoch Sanders, Liverpool University; Malcolm Catchick Sarkies, Henry Mearns Savery and Walter Manley Savery, Middlesex Hospital; Ernest Algernon Sparks, St. Thomas's Hospital; Victor Alexander Trevor Spong, St. Bartholomew's Hospital; Graham McKim Thomas, Guy's Hospital; John Henry Tighe, Birmingham University; Bertie Moorwood Tonkin, Guy's Hospital; William Stephen Tunbridge, Oxford University and St. Bartholomew's Hospital; Jacob Eliza de Villiers Van der Merwe, Guy's Hospital; Frederic Francis Wheeler, St. Mary's Hospital; Herbert Edward Williams, London Hospital; and Robert Wolff, Middlesex Hospital.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At the Preliminary Science Examination for the Licence in Dental Surgery, held on March 28th, 29th, 30th, and 31st, the following candidates were successful:—

Chemistry and Physics.—Alfred Meredyth Bennett, Westminster School; John Heath Broadhead, Technical College, Darlington, and Bootham School, York; Christopher Egbert George Busbridge, Plymouth Technical School; Harold Edward Fussell, County School, Wrexham; Graham Murray-Shirreff, Bristol University; Harry Sydney Kemp Seal, University College; Victor Leslie Simpson, Polytechnic Institute; William Sandford Wald, Eastern District Secondary School, Douglas; John William Ernest Warren, Birkbeck College; James Andrew Whittle, Royal Dental Hospital; Norman Bulst Wells, Municipal College, Bournemouth; and Frank Woodford, Guy's Hospital.

Chemistry.—John William Kewley Cain, Eastern District Secondary School, Douglas; and Allistair Hyland Grieve, Birkbeck College.

Physics.—William Thomas Lloyd Douglas, London Hospital; and Thomas Edward Hoggins, Birmingham University.

SOCIETY OF APOTHECARIES OF LONDON.—At examinations held recently the following candidates were successful:—

PRIMARY EXAMINATION, PART II.

Anatomy.—W. M. Anthony, St. Thomas's Hospital; G. R. Aspinwall, Cambridge and Guy's Hospital; W. A. Bibby, Manchester; T. L. Bonar, Cambridge and Middlesex Hospital; J. Brodetsky, London Hospital; K. R. Chapple, St. Bartholomew's Hospital; E. S. Davies and D. A. Dyer, King's College; J. Gordon, Leeds; J. Gorsky, King's College; W. R. G. Harris, London Hospital; R. A. Hickley, St. Mary's Hospital; A. R. Hill and O. S. Hillman, Middlesex Hospital; C. Holmes, Liverpool; R. E. Jenkins, London Hospital; E. F. J. Jones, Cardiff; R. M. Jones, Liverpool; F. W. Kemp, Charing Cross Hospital and King's College; N. H. Kettlewell, Bangor and Middlesex Hospital; W. Kilroe, Guy's Hospital; P. Lloyd Williams, St. Thomas's Hospital; L. Lyne, Guy's Hospital; J. J. M. MacDonnell and J. S. Moore, St. Thomas's Hospital; G. S. Morgan, Oxford and London Hospital; H. S. Morris, Guy's Hospital; W. R. Ranson, Middlesex Hospital; G. V. Richards, Guy's Hospital; S. Robinson, Belfast; A. H. Shelswell and H. W. Southgate, Guy's Hospital; E. A. Sparks, St. Thomas's Hospital; J. Stephen, Manchester; A. C. Teuten, St. Mary's Hospital; C. de B. Thomson, Middlesex Hospital; and A. E. Young, Bristol.

Physiology.—W. M. Anthony, St. Thomas's Hospital; G. R. Aspinwall, Cambridge and Guy's Hospital; J. Brodetsky, London Hospital; E. S. Davies and J. Gorsky, King's Hospital; W. R. G. Harris, London Hospital; A. R. Hill and O. S. Hillman, Middlesex Hospital; C. Holmes, Liverpool; R. E. Jenkins, London Hospital; E. F. J. Jones Cardiff; F. W. Kemp, Charing Cross Hospital and King's College; J. S. Lewis, St. Mary's Hospital; P. Lloyd-Williams, St. Thomas's Hospital; L. Lyne, Guy's Hospital; J. J. M. MacDonnell and J. S. Moore, St. Thomas's Hospital; G. E. Morgan, Oxford and London Hospital; H. S. Morris, Guy's Hospital; W. R. Ranson, Middlesex Hospital; G. V. Richards, A. H. Shelswell, and H. W. Southgate, Guy's Hospital; E. A. Sparks, St. Thomas's Hospital; A. C. Teuten, St. Mary's Hospital; and A. E. Young, Bristol.

PRIMARY EXAMINATION, PART I.

Biology.—K. J. H. Davies, Guy's Hospital; and H. T. M. Price, Birmingham.

Chemistry.—K. J. H. Davies, Guy's Hospital.

Materia Medica and Pharmacy.—L. E. A. B Farr, Cambridge and King's College Hospital; and T. F. Reason, St. Mary's Hospital.

LONDON SCHOOL OF TROPICAL MEDICINE.—At the examination of this school at the termination of the fiftieth session (January-April, 1916) the following candidates were successful:—

W. N. Leak (distinction, highest marks, Duncan medal), H. Bayon (distinction), Miss V. G. Field, E. A. Blok, and J. A. Beels.

UNIVERSITY OF MANCHESTER.—The following has obtained the Diploma in Public Health: Harold Heathcote, M.B., Ch.B. Manch.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH, ROYAL COLLEGE OF SURGEONS OF EDINBURGH, AND ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—At examinations held recently the following candidates were successful:—

FIRST EXAMINATION.

Thomas Arnoldus du Toit, Robert Berry Forgan, William Harvie Kerr, Richard Francis Kerr, Lizzie Robertson Clark, Mayberry Hugh Carleton, Jung Bahadur Singh, and George Coote Field.

Biology.—Peter Edwin Malloch.

Chemistry.—John Murray and Andrew Wood Smith.

SECOND EXAMINATION.

Albert Ernest Hempleman, Reginald Edward Hopton, Arthur Stanley Hughes, Eduard Louis Arendorff, Rebecca Goodman, John Kohler Steel, and William Gibb.

Anatomy.—Hugh William Howatson.

Physiology.—Jacob Johannes van Niekirk, Gordon Spivey Woodhead, and James Foster Cook.

THIRD EXAMINATION.

Cecil Vale Samwell, Ernest Ebenezer Bronstorph, George Patrick de Silva, Henry Shaw, Andrew Inglis Meek, and Christopher Robert Cecil Moon.

Pathology.—Mahmoud Abdel Kader Mofreh, Eliza Jean Stuart, Patabendimuhandirange Martin Fernando, and Donald Stewart.

Materia Medica.—Daniel Cornelius Howard.

FINAL EXAMINATION.

Zachariah Albert Green, James Edward Ainsley, John Cardew Bedwell, Harold Cranwell Aloysius Haynes, Bertram Conrad Haller, James Byrne, James Virgil Reynolds Rohan, Salamon Julius Abrahams, James Blackburn, Charles Harris, Andrew Gaston, and Robert Christian Wilson Spence.

Medicine.—Stanley Wall Hoyland.

Surgery.—John Joseph Curtin.

Midwifery.—John Adami and John Joseph Curtin.

Medical Jurisprudence.—John Herbert Blackburn, Reginald Vincent Clarke, Charles George Book, William McElroy, and Maurice Andrew White.

UNIVERSITY OF GLASGOW.—At the Fourth (Final) Professional Examination for the Degree of M.B., Ch.B., the following candidates were successful:—

*William Dick Allan, John Alston, William Baird, Christina Blair Buchanan, Duncan Cameron, *Joseph Chalmers, Douglas Hamilton Coats, William Kerr Connell, Alexander Finlay Cook, Archibald Shankland Cook, Walter Gow Cook, John Norman Cruickshank, Andrew Davidson, Jane Beattie Davidson, *John Dunbar, James Brown Fisher, Matthew Mair Frew, Thomas Ronald Fulton, William Hamilton Gibson, Jessie Crawford Gilchrist, John Glaister, James Scott Kinross, †George Kirkhope, William Joseph Brown Lavery, Robert Linfay, M.A., Dorothy M'Cubbin, James Wallace Maclarlane, John MacInnes, Keith Stuart Macky, Duncan M'Laren, Elizabeth Stewart Martin, Frederick Robertson Martin, James M'Donald Matheson, William Watson Morrison, Alexander Morton, William O'Brien, James Alexander Paterson, Thomas Smith Paterson, James Herbert Paul, M.A., B.Sc., William James Poole, Thomas Joseph Desmond Quigley, James Richardson, Alexander Wilkie Ritchie, George William Ronaldson, *Mary Helen Routledge, Mary Isabel Sinclair, ‡Jane Stalker, William Mitchell Stewart, John Lawrence Torley, Robert Smellie Weir, *Clive Alan Whittingham, and *Marion Baillie Darling Wilson.

* Distinguished in Midwifery.

† Distinction in Surgery and Clinical Surgery.

‡ Distinction in Medicine and Clinical Medicine.

TYPHOID FEVER ALONG THE SHANNON.—During the past winter, as in several successive years, large stretches of country on either side of the Shannon have been flooded, and for several weeks the homesteads on the banks have been submerged in several feet of water and have been evacuated. On the return of the inhabitants to their homes this year an outbreak of typhoid occurred in the recently flooded areas near Athlone.

ROYAL COMMISSION ON UNIVERSITY EDUCATION IN WALES.—His Majesty the King has been pleased to approve the appointment of a Royal Commission on University Education in Wales. The terms of reference of the Commission are as follows: "To inquire into the organisation and work of the University of Wales and its three constituent colleges, and into the relations of the University to those colleges and to other institutions in Wales providing education of a post-secondary nature, and to consider in what respects the present organisation of university education in Wales can be improved, and what changes, if any, are desirable in the constitution, functions, and powers of the University and its three colleges." The following are the names of the persons appointed to serve on the Commission: The Right Hon. Viscount Haldane of Cloan, O.M., K.T., F.R.S., LL.D., chairman; Professor W. H. Bragg, F.R.S., M.A., D.Sc., Quain professor of physics in the University of London; the Hon. W. N. Bruce, C.B., a principal assistant secretary under the Board of Education; Sir Owen M. Edwards, M.A., Chief Inspector of the Welsh Department of the Board of Education; W. H. Hadow, M.A., D.Mus., Principal of Armstrong College, Newcastle; A. D. Hall, M.A., F.R.S., a Commissoner under the Development Act; Sir Henry Jones, M.A., LL.D., D.Litt., professor of moral philosophy in the University of Glasgow; Sir William Osler, Bart., F.R.S., M.D., D.Sc., LL.D., D.C.L., Regius professor of medicine in the University of Oxford; and Miss Emily Penrose, M.A., Principal of Somerville College, Oxford. The secretary to the commission is Mr. A. H. Kidd, of the Board of Education, to whom all communications should be addressed.

PETROL CONSUMPTION BY IRISH MEDICAL MEN.—An inquiry has been issued from the office of the Lord Lieutenant of Ireland to all medical men, who are asked to state on a form their consumption of motor spirit and the type of car or motor cycle used by them. After these returns have been collected it will be decided what amount of spirit each medical practitioner will be entitled to receive during war time.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

The Local Government (Emergency Provisions) Bill.

Two clauses in this Bill have special relation to medical men. One of these clauses, provisions as to the notification of diseases, reduces the fee payable to a practitioner for the notification of a case of infectious disease from half-a-crown to one shilling. When the Bill was in Committee in the House of Commons on Tuesday, Sir PHILIP MAGNUS moved an amendment to the effect that the fee should remain unchanged except in the case of measles. Mr. HAYES FISHER, the Parliamentary Secretary to the Local Government Board, resisted the amendment. The proposal to reduce the fee came from the Retrenchment Committee, and he was afraid that he could hold out no hope that the Local Government Board would forego the clause, at any rate for the period of the war. The amendment was negatived without a division and the clause was agreed to.

The text of the clause is in the following terms: "Notwithstanding anything in the Infectious Diseases (Notification) Act, 1889, or in any other Act, or in any Order of the Local Government Board, the following provisions shall have effect: (*a*) The fee to be paid to a medical practitioner for a certificate or notification sent by him to a medical officer of health in respect of a case of disease to which the Act or Order applies, occurring in his private practice, shall be one shilling and no more; (*b*) Every case of infectious disease occurring in any building, tent, van, shed, or similar structure in the occupation of any of His Majesty's forces, or of any person employed by or under the Admiralty, the Army Council, or the Minister of Munitions shall be notified to the medical officer of health of the district by the medical attendant if it would have been his duty to notify it if it had occurred elsewhere; and the local authority shall pay to the medical attendant (unless he is a medical officer or practitioner who holds a commission in any of His Majesty's forces or is employed by the Admiralty or Army Council and is prohibited from engaging in private practice) for the certificate or notification a fee of one shilling, whether the case occurs in his private practice or otherwise."

Another clause in the Bill has reference to the payments by county councils in respect of the salaries of medical officers. It runs:—"If a temporary substitute is appointed with the sanction of the Local Government Board to replace any medical officer of health or inspector of nuisances who has been granted leave of absence in accordance with the provisions of this Act to serve in or with His Majesty's forces, the county council shall be liable under paragraph (c) of subsection (2) of section twenty-four of the Local Government Act, 1888, to pay to the local authority one half of the sum actually paid by the local authority to the medical officer or inspector of nuisances so replaced or his wife or other dependants nominated by him under this Act, and of the salary of the temporary substitute as sanctioned by the Local Government Board, taken together."

The Bill has passed through Committee and been reported with amendments to the House.

HOUSE OF COMMONS.

WEDNESDAY, APRIL 5TH.

Royal Commission on Venereal Diseases.

Mr. KING asked the Chief Secretary to the Lord Lieutenant of Ireland whether his attention had been drawn to the recommendations in the report of the Royal Commission on Venereal Diseases with respect to the examination of prisoners; whether it was his intention to carry them into effect in Ireland, and whether he would give an undertaking that no female prisoner or female person detained in a Borstal institution would be locally examined except by a woman doctor.—Mr. BIRRELL wrote in reply: So far as the General Prisons Board for Ireland is concerned no difficulty will be made in giving effect to the recommendation of the Royal Commission on Venereal Diseases that where the medical officer of a prison considers that an examination of a woman is necessary, it should only be made by a woman doctor. In the only prison that is wholly occupied by women prisoners in Ireland the medical officer is a woman.

THURSDAY, APRIL 6TH.

Artificial Limbs for Soldiers and Sailors.

Mr. FORSTER (Financial Secretary to the War Office) informed Mr. W. THORNE that artificial limbs were supplied in kind at Government expense to disabled soldiers and sailors, and the recipients were fully maintained in hospital at public expense while they were being fitted.

The Health of Munition Workers.

Replying to Major ASTOR, Dr. ADDISON, Parliamentary Secretary to the Ministry of Munitions, said: The girls and women at Messrs. Vickers's works at Erith, who have been recently changed from the three-shift to the two-shift system, were not medically examined prior to making this change. There is, however, a qualified medical man in residence close to the works who has been specially appointed to look after the health of all the firm's workers, and he has a surgery, first-aid station, and the assistance of a qualified nurse.

Major ASTOR asked the honourable gentleman how many controlled establishments where women were employed had changed from three 8-hour shifts to two 12-hour shifts since the recommendations of the Health of Munition Workers Committee recommending 8-hour shifts were published.—Dr. ADDISON answered: So far as I am aware only one establishment—namely, Messrs. Vickers, Limited, of Erith, have changed their system of shifts for their women employees from a three to a two-shift system since the issue of the Health of Munition Workers Committee's memorandum on the subject of hours of work. My honourable friend should understand that under the system introduced there work is confined to six days a week, and that the total working hours per week are from 58 to 60. One of the chief reasons which induced the Minister of Munitions to agree to this experiment, after a careful report by a leading Home Office inspector, was that the weekly rest time was increased from 16 continuous hours to 26 in each of the first two weeks, and from 24 to 48 in the third week.

Mr. ASHLEY: Surely 60 working hours a week are too much for girls to work even on munitions?—Dr. ADDISON: I agree, but that is within the limits of the Home Office regulations and the Munition Workers Committee's recommendations.

Mr. LEWIS HASLAM asked whether the recommendations of the Health of Munition Workers Committee with regard to ventilation and mechanical devices for ensuring workers against the inhalation of poisonous fumes, &c., were being carried out with the coöperation and under the guidance of the factory inspectors' department at the Home Office.—Dr. ADDISON said in reply: The precautions in question recommended by the Committee are, I understand, already being enforced by the inspectors of the factory department of the Home Office as a part of their general administration.

Dr. ADDISON, replying to a further question by Mr. HASLAM, stated that the exercise of compulsory powers to prevent the continuance of evils indicated in the reports of the Committee had not been hitherto found necessary, but if occasion arose the Minister of Munitions was prepared to take this course.

The Navy Medical Service.

Mr. ANEURIN WILLIAMS asked the Secretary to the Admiralty how many qualified medical men were now employed in connexion with the navy.—Mr. MACNAMARA wrote in reply: The number employed is 1118. This does

not include part-time medical men—namely, Admiralty surgeons and agents.

Vaccination in the Army.

Mr. TENNANT (Under Secretary for War) informed Mr. CHANCELLOR that no instructions for curtailment of leave to men in connexion with refusal of vaccination had been issued by the War Office.

Sickness at Oswestry Camp.

Sir F. CAWLEY asked the Under Secretary for War how many cases of sickness there had been at the Oswestry camp during the last six months; how many deaths had taken place either at the camp or from sickness contracted there; what was the total number of recruits in training at this camp; and what were the arrangements for dealing with cases of sickness, including medical staff and hospital accommodation.—Mr. TENNANT (in a written answer) replied: The average strength at the Oswestry camp during the last six months has been 9269. During that period there have been 1099 admissions to hospital and 27 deaths have taken place. The arrangements for dealing with cases of sickness and the scale of hospital accommodation are on the same scale as at other camps.

The Motor-car Licence Duty.

Mr. KING asked the Chancellor of the Exchequer to state, in connexion with the increased taxation on motor-cars, when it was proposed that this tax shall be payable; and whether it would be collected by and paid into the accounts of the local authorities.—Mr. MCKENNA replied: No alteration is proposed as regards the date on which motor-car licence duty is payable, but a supplementary licence for the remainder of the current calendar year will have to be taken out before June 30th or August 15th for cars, &c., which it is proposed to use after these dates. The new duties will, like the existing duties, be collected by the local authorities on behalf of the Exchequer.

Mr. D. M. MASON: Does the tax apply only to cars which are used?—Mr. MCKENNA: I should imagine the local authority would insist upon the surrender of the number of the car in order to prevent it being used.

Mr. WING: Does the answer of the right honourable gentleman apply to commercial cars?—Mr. MCKENNA: No.

MONDAY, APRIL 10TH.

Non-poisonous Dopes.

Replying to Mr. ROWLANDS, Mr. BRACE (Under Secretary for the Home Department) said: The Department are issuing all the non-poisonous dopes which they possess, and if they can possibly get a larger supply they will discontinue the poisonous. I can assure my honourable friend that we are doing everything we can in the matter.

Motor-car Tax.

Mr. MCKENNA (Chancellor of the Exchequer) informed Mr. ROWLANDS that he was considering whether exemption from the new duty could not be granted for motor-cars which were exclusively used for such purpose as the Red Cross, Special Constabulary, Voluntary Aid Detachment, and other voluntary work for the Government.

Sir FORTESCUE FLANNERY: Will the right honourable gentleman make a similar concession with regard to cars of registered medical practitioners necessary for carrying on their work?—Mr. MCKENNA: I should like to have notice of any question with regard to making concessions on the Budget.

Territorial Medical Officers.

Mr. LYNCH asked the Under Secretary for War whether he had heard of any discontent amongst Territorial medical officers, especially those attached to regiments; and whether he would consider the appointment of a Territorial medical officer of position and long service as such on the staff of the Director-General at the War Office and the insertion in the Army List of a seniority list of the officers of the Territorial medical service.—Mr. TENNANT wrote in reply: The Territorial regimental medical officers joined the service for the specific purpose of doing the duties in which they are now engaged and it is unlikely that they would be discontented if called upon in time of war to assume responsibilities for which they engaged in time of peace. Promotion of regimental medical officers is regulated by time service. Other Territorial Force medical officers are promoted by selection and seniority in their units. In these circumstances there is no need for a seniority list. The Director-General has on his staff an officer who has considerable experience of the Territorial Force.

Mr. LYNCH asked the right honourable gentleman whether a lieutenant-colonel of the Territorial medical service of many years' service received the same remuneration as a temporary lieutenant-colonel appointed since the commencement of the war; if so, whether this was in accordance with the spirit of the War Office undertaking that such officers should receive the pay of the corresponding rank as laid down by the Pay Warrant, 1914, for officers of the Royal Army Medical Corps; whether in the case of such officers their experience and their services were held to make them more valuable; and whether the higher rate of pay of 35s. laid down in the warrant for lieutenant-colonels of the Royal Army Medical Corps would be given them after five years' service in the ranks.—Mr. TENNANT (in a written answer) replied: Yes, sir, these officers are treated in accordance with the undertaking referred to. Unmobilised service in the Territorial Force cannot be held to count towards the higher rate of pay as if it were full-pay service in the Regular Army. If any Territorial Force lieutenant-colonels give the necessary amount of embodied service they will be entitled to the higher rate of pay.

WEDNESDAY, APRIL 12TH.

Medical Men and Increased Motor Licences.

Sir CLEMENT KINLOCH-COOKE asked the Chancellor of the Exchequer whether it was proposed to make any concession to medical men in respect of the increased licences on motors and motor cycles.—Mr. MCKENNA replied: The existing concession under which registered medical practitioners pay only half rates will extend to the new duties.

Appointments.

Successful applicants for vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward to THE LANCET Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, such information for gratuitous publication.

LINDSAY, JOHN KERR, L.R.C.P. & S. Edin., L.F.P.S. Glasg., has been appointed a District Medical Officer by the Bristol Board of Guardians.

TURNER, W., M.S. Lond., F.R.C.S. Eng., has been appointed Surgeon to In-patients at Westminster Hospital.

Vacancies.

For further information regarding each vacancy reference should be made to the advertisement (see Index).
When the application of a Belgian medical man would be considered the advertisers are requested to communicate with the Editor.

BATH, WINSLEY SANATORIUM.—Assistant Resident Medical Officer, unmarried. Salary £250 per annum, with board, residence, and laundry.

BELGRAVE HOSPITAL FOR CHILDREN, Clapham-road, S.W.—Resident Medical Officer for six months. Salary at rate of £100 per annum, with board, residence, and washing.

BRISTOL GENERAL HOSPITAL.—House Physician for six or three months. Salary at rate of £175 per annum, with board, residence, &c.

BRISTOL ROYAL INFIRMARY.—House Physicians and House Surgeons. Salary at rate of £120 per annum, with board, apartments, and laundry.

BROOK WAR HOSPITAL, Shooter's Hill, Woolwich.—Resident Medical Office. Salary £1 daily, with board and residence

BURNLEY, VICTORIA HOSPITAL.—Female House Surgeon. Salary £160 per annum, with residence, board, and washing.

BURY INFIRMARY.—Senior House Surgeon. Salary £250 per annum, with board, residence, and washing.

CAMBRIDGESHIRE ASYLUM, Fulbourn, near Cambridge.—Junior Assistant Medical Officer, unmarried. Salary £200 per annum, with board, lodging, washing, and attendance.

CHESTERFIELD AND NORTH DERBYSHIRE HOSPITAL.—Second House Surgeon. Salary £150 per annum, with board, apartments, and laundry.

COBHAM, SURREY, SCHIFF HOME OF RECOVERY, Knowle Hill Park.—Resident Surgical Officer for six months. Salary at rate of £200 per annum, with board, lodging, and washing.

DERBY, DERBYSHIRE ROYAL INFIRMARY.—House Physician and Casualty Officer. Salary £200 per annum, with board, residence, &c.

FEDERATED MALAY STATES.—Female Medical Officer. Salary £360 per annum.

GALWAY HOSPITAL.—Resident Medical Officer and Compounder of Medicine. Salary £100 per annum, with apartments and rations.

GREAT NORTHERN CENTRAL HOSPITAL, Holloway-road, N.—House Physician for three months. Salary at rate of £100 per annum, with board, residence, and laundry.

HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST, Brompton.—House Physician for six months. Salary 30 guineas.

LEEDS PUBLIC DISPENSARY.—Female Resident Medical Officer. Salary £130 per annum, with board, residence, and laundry.

LIVERPOOL, TOWNSHIP OF TOXTETH PARK POOR-LAW INSTITUTION AND INFIRMARY.—Assistant Resident Medical Officer. Salary £300 per annum, with board, washing, and apartments

LIVERPOOL, URBAN DISTRICT COUNCIL OF WATERLOO-WITH-SEAFORTH.—Medical Officer of Health and School Medical Officer. Salary £130 and £100 per annum respectively.

LONDON HOSPITAL.—Two Vacancies on Assistant Obstetric Staff.

LONDON TEMPERANCE HOSPITAL, Hampstead-road, N.W.—Assistant House Surgeon for six months. Salary at rate of 120 guineas per annum.

MANCHESTER, HULME DISPENSARY, Dale-street, Stretford-road.—House Surgeon. Salary £250 per annum, with apartments, attendance, coal, and gas.

MANCHESTER NORTHERN HOSPITAL FOR WOMEN AND CHILDREN, Parkplace, Cheetham Hill-road.—Female House Surgeon. Salary £120 per annum, with apartments and board.

MANCHESTER ROYAL INFIRMARY.—Resident Medical Officer and Resident Surgical Officer. Salary £225 per annum each. Also Assistant Resident Surgical Officer, Accident Room House Surgeon, and Resident Medical Officer (Central Branch). Salary £200 per annum in each case.

NEW HOSPITAL FOR WOMEN, Euston-road, N.W.—Female Temporary Assistant Surgeon for six months.

NEWCASTLE-UPON-TYNE, ROYAL VICTORIA INFIRMARY.—Four Resident House Physicians, Four Resident House Surgeons, Resident Accident Room House Surgeon, Resident House Surgeon to Aural and Ophthalmic Department, Resident House Surgeon to Skin and Gynæcological Department, and Resident House Surgeon to Outpatient Dressing Department.

NORTHAMPTON GENERAL HOSPITAL.—Two House Surgeons. Salary £150 per annum each, with apartments, board, washing, and attendance.

PUTNEY HOSPITAL, Lower Common, S.W.—Resident Medical Officer. Salary £150 per annum, with rooms, board, and laundry.

QUEEN'S HOSPITAL FOR CHILDREN, Hackney-road, Bethnal Green, E.—House Surgeons for six months. Salary £100 per annum, with board, residence, and washing.

ROCHESTER, ST. BARTHOLOMEW'S HOSPITAL, Kent.—Senior Resident House Surgeon. Salary at rate of £300 per annum.

SALISBURY GENERAL INFIRMARY.—Assistant House Surgeon, unmarried. Salary £100 per annum, with board, lodging, and washing.

SHEFFIELD, JESSOP HOSPITAL FOR WOMEN.—Female Junior House Surgeon, unmarried. Salary £80 per annum, with board, residence, and laundry.

SHEFFIELD ROYAL INFIRMARY.—House Physician. Salary £120 per annum, with board and residence.

SOUTHAMPTON FREE EYE HOSPITAL.—House Surgeon. Salary £100 per annum, with board, lodging, and laundry.

VENTNOR, ISLE OF WIGHT, ROYAL NATIONAL HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST.—Assistant Resident Medical Officer.

VICTORIA HOSPITAL FOR CHILDREN, Tite-street, Chelsea, S.W.—House Surgeon. Salary at rate of £200 per annum, with board and lodging.

WARWICKSHIRE AND COVENTRY JOINT COMMITTEE FOR TUBERCULOSIS.—Resident Medical Officer for Bramcote Sanatorium, near Nuneaton. Salary at rate of £250 per annum, with board, &c.

WEST HAM AND EASTERN GENERAL HOSPITAL, Stratford, E.—House Physician.

WINCHESTER, ROYAL HAMPSHIRE COUNTY HOSPITAL.—Female Assistant House Surgeon. Salary £100 per annum, with residence, board, and washing.

THE Chief Inspector of Factories, Home Office, London, S.W., gives notice of a vacancy for a Certifying Surgeon under the Factory and Workshop Acts at St. Faith's, in the county of Norfolk.

Births, Marriages, and Deaths.

BIRTHS.

COX.—On April 9th, at 8, Ellerdale-road, Hampstead, to Dr. and Mrs. R. J. H. Cox, C.M.S., Bannu, N.W.F.P., India, a daughter.

DYKES.—On March 28th, at the Nursing Home, College-avenue, Maidenhead, the wife of T. Campbell Dykes, L.D.S., Dental Surgeon, of a daughter.

REICHARDT.—On April 4th, at Dorset House, Ewell, Surrey, the wife of E. N. Reichardt, M.D. Lond., of a son.

WHEATON.—On April 9th, at Rastell-avenue, Streatham-hill, S.W., the wife of S. W. Wheaton, M.D. Lond., F.R.C.P. Lond., of a daughter.

MARRIAGES.

DENHAM—BRIGGS.—On April 11th, at Trinity Presbyterian Church, Kensington, Captain Charles Holmes Denham, R.A.M.C., to Irene, youngest daughter of the late James Cronshaw Briggs, of The Firs, Cheadle, Cheshire.

HARTY—CLARK.—On April 8th, at All Saints Church, Notting-hill, John Percy Ingham Harty, M.B. Irel., F.R.C.S. Eng., Captain, R.A.M.C. (T.), to Helen Dorothy, second daughter of Mr. and Mrs. J. G. Clark, of Ladbroke-gardens, W.

JOHNSTONE—GRAHAME.—On April 4th, at St. Columba's, S.W., Thomas Johnstone, M.D. Edin., M.R.C.P. Lond., of Harrogate, to Agnes Mary Grahame, of Ripon, daughter of the late John Anthony Grahame, of Westminster and Sussex-gardens, W.

SMITH—ACKERLEY.—On April 6th, at St. Matthew's Church, Surbiton, Austin Nimmo Smith, Captain, R.A.M.C., to Muriel Alice, daughter of Dr. R. Ackerley, of Llandrindod Wells.

SMITH—MALLINSON.—On April 11th, at Walthamstow, Philip Smith, Captain, R.A.M.C., to Evangeline Dorothea, younger daughter of William Mallinson, J.P., of The Limes, Walthamstow.

DEATHS.

BLADES.—On April 9th, at 182, Clapham-road, Charles Corbett Blades, M.D., in his 82nd year.

BRICE.—On April 5th, at Swansea, Major Ernest Brice, R.A.M.C., M.R.C.S., aged 52 years.

COLE.—On April 11th, of wounds received on March 22nd, Major A. H. Cole, F.R.C.S., aged 46 years.

PHELPS.—On April 8th, at Baxter-gate, Loughborough, Philip Phelps, M.R.C.S. Eng., F.R.C.P. Edin., L.M., aged 63 years.

POWELL.—On April 5th, H. FitzGerald Powell, M.D. St. And., F.R.C.S. Edin., Surgeon, Throat Hospital, Golden-square, W.

KILLED ON DUTY.

NICHOL.—On April 5th, accidentally killed while flying at night on the North-East Coast of England, John Nichol, aged 22. Lieutenant, Royal Scots Fusiliers, and Flying Officer, Royal Flying Corps, second son of Dr. and Mrs. Nichol, of Margate.

N.B.—A fee of 5s. is charged for the Insertion of Notices of Births, Marriages, and Deaths.

Notes, Short Comments, and Answers to Correspondents.

CHOLERA IN THE MALAY STATES.

REPORTS for the year 1914 on the States of Kedah, Perlis, Kelantan, and Trengganu have been laid before the Houses of Parliament. The territories in question are portions of the Malayan Peninsula not included in the Federated Malay States, but the rights of their protection, administration, and control were transferred by Siam to Great Britain by the Anglo-Siamese Treaty of March 10th, 1909. Kedah, which lies on the west coast of the Peninsula, and includes the Langkawi group of islands, has an area of 3800 square miles and an estimated population of 250,000. The capital is Alor Star, eight miles inland on the Kedah River, with a population of about 12,000. There are 38 British officials employed in the public works, survey, police, and medical departments. The acting British adviser to the Kedah Government is Mr. L. E. P. Wolferstan, whose report gives special attention to the outbreaks of cholera which have occurred in the State from 1907 to 1914. He quotes the following extracts as to these from a report made by Dr. A. L. Hoops: "First epidemic (August to September, 1907). The disease began after a long spell of dry weather in what is usually a wet season. 333 cases were recorded, and 247 deaths. Probably at least double the number of cases and deaths occurred. The epidemic did not spread much outside Alor Star and Kuala Kedah. Second epidemic (March and April, 1908). This was more widespread; 125 cases were reported from Kuala Muda district out of 686, with 541 deaths. Third epidemic (February to July, 1911). 1211 cases recorded with 966 deaths. Cases were better reported than formerly. It is calculated that at least 1500 deaths were caused by the disease. Alor Star and environs suffered severely. Most of North Kedah was attacked, and Langkawi Island suffered for the first time. Fourth epidemic. This really started in November, 1913, with 11 cases in Alor Star and Kuala Kedah. Unlike previous outbreaks, it began after an excellent wet season and before the rains ceased, but only became serious when drought set in. 2196 cases were recorded and 1502 deaths. Few places escaped; the disease spread to Kuala Muda, in South Kedah, and up stream to Baling. Undoubtedly there was a good deal of concealment, mainly in Kuala Muda and Baling districts. Though the deaths in these districts exceeded the deaths of the year before by 1051, only 325 were returned as due to cholera."

Mr. Wolferstan's report proceeds as follows:—"It is a conservative estimate that there have been 5500 deaths from cholera in Kedah in the past eight years out of a total of 37,000 from all causes—that is to say, cholera is responsible for nearly 15 per cent. over the whole period. In 1914 one-third of the deaths were due to cholera. The State surgeon says that he is convinced cholera has not been imported into Kedah, though some medical textbooks give it as a truism that cholera is an imported disease. None of the outbreaks in Kedah has been traced to an imported cause. Conditions in Alor Star favour the life of the cholera bacillus owing to the nature of the river and shallow well water, while the clay subsoil forms an ideal culture medium for its growth. Dr. A. J. Stanton, of the Medical Institute, Kuala Lumpur, visited Alor Star in April, 1914, and on his return to Kuala Lumpur made some interesting experiments with water drawn from the Wan Mat Canal, which is practically Alor Star river water. Emulsions of cholera bacilli from a Kedah case were added to samples of this water; it was found that even when the water was previously sterilised vibrios grew and multiplied rapidly in it. On the contrary, emulsions added to Kuala Lumpur tap-water (unsterilised) rapidly died out. Dr. Stanton concludes that Alor Star water itself contains ingredients favourable to the spread of cholera. He forms the hypothesis that there is within certain areas in Kedah a natural reservoir of virus, the renewed activity of which is derived from some special combination of circumstances. During the epidemic drinking of river water was forbidden; no bathing water was allowed to be carried to houses. Sikh guards were detailed to enforce restrictions. In 1911 an iron catchment area had been erected for collecting rain-water, with tanks holding 480,000 gallons of water. Drinking water was supplied from the tanks, and when this source failed 70 tons of drinking water were brought daily from Penang. Part was pumped into tanks at Kuala Kedah for use of surrounding villages. For the railway coolies special tanks were constructed and water boiled and supplied from them. An assistant surgeon and four dressers were sent by the Railway Department to assist.

Dr. J. H. Tennent, from the colony, was lent to help in combating the disease. The State surgeon himself fell a victim, and was laid up for a month. ..... At Christmas-time cholera started in the Wong; this followed on a debauch on toddy amongst a number of Tamils; 21 cases in all occurred." The report goes on to record the completion of new waterworks, adding the comment: "That cholera will not break out in Alor Star again in the future can hardly be hoped, but, if the same success attends the provision of a good supply of water in Alor Star as was the case in Malacca some years ago, it may be hoped that the disease will never assume an epidemic form of considerable magnitude."

The report on the State of Perlis (area 300 square miles, population 32,740) mentions that cholera broke out in March, 1914; there were 45 cases, with 40 deaths. The outbreak came to an end in June. The infection came from Kedah. There appear to have been no corresponding outbreaks either in the State of Kelantan or the State of Trengganu.

The principal diseases, apart from cholera, prevalent in Kedah during the year were dysentery, ankylostomiasis, and malarial fever. In Perlis the chief ailments treated in the Government dispensary were malaria and skin diseases. In Kelantan the diseases mostly causing admission to hospital were dysentery (80), beri-beri (33), malaria (124), venereal diseases (172), and ankylostomiasis (40). Of 14,073 out-patients, 1115 Malays and 345 of other nationalities were treated for venereal diseases. Mr. C. N. Maxwell, the British Agent in Trengganu, observes in his report: "The Bundi Tin Mining Syndicate employ a qualified medical man on the mine in Ulu Kemaman. There is no other qualified doctor in the State (which has an area of 6000 square miles and a population of 154,037). There is a considerable amount of disease, and I am occasionally informed of deaths from cholera, small-pox, fever, and dysentery. A large number of people suffer from skin disease, and many of the children are disfigured with yaws and other eruptive complaints. Sanitation does not exist. Fortunately there were no serious epidemics during the year. I am occasionally asked for medicines, which I provide in simple cases. A matter to which I have drawn the Sultan's attention is the absence of any proper burial-grounds. Corpses are buried anywhere and everywhere, and Kuala Trengganu is one vast burial-ground with graves at every few yards."

NOTIFICATION FEES AND THE CERTIFICATE QUESTION.

A CORRESPONDENT writes: "In the matter of opposing the proposed reduction in notification fees (from 2*s.* 6*d.* to 1*s.*), this is not a time for attacking the much-harassed medical profession. If we agree to this reduction, no doubt in a few years we shall be compelled, as in the case of notification of births, to give all certificates without any payment. I foresee the time when 2*s.* 6*d.* will be regarded as a munificent fee for a doctor in general practice. Our expenses are increasing by leaps and bounds, while our emoluments are one by one disappearing." We have not quite the same gloomy forebodings as the writer of this letter. That a medical man would give his services, to say nothing of a written record of them in the shape of a certificate, gratuitously was commonly assumed a few years ago. Our legislators now know a little better. During the war the medical practitioner is certainly bound to suffer, and the efforts of all must be directed towards equalising a general burden. The prospects of practice after the war seem to us brighter than they do to our correspondent.

MR. H. G. WELLS AND DOCTORS.

To the Editor of THE LANCET.

SIR,—What is the matter with Mr. Wells? In the *Daily Mail* of April 8th he says the Government has refused the offer of Mr. Barker to treat injured men in the present war. May I point out that by S. 36 of the Medical Act, 1858, it is provided that "no person shall hold any appointment ..... in the Military or Naval Service ..... unless he is registered under this Act." Cannot Mr. Wells induce Mr. Barker to take a registrable medical diploma?

Mr. Wells next describes the medical profession as a "trade union." I wish he would make it a union! Many doctors now find how difficult it is to obtain a living, because so many *well-to-do* people obtain *free* treatment from Poor-law infirmaries, voluntary hospitals, municipal fever hospitals, sanatoria for consumptives, free vaccination, free school examination, and cheap panel doctors. Would any skilled craftsman have anything to do with schemes which supplied free labour to the public? Would they agree to work for the same wages on Sundays and on night work? Not likely. Would skilled union craftsmen agree to give their services at a few shillings a year on a panel system? Mr. Wells is in error in referring to the "atrocious incapacity of the general practitioner"—a term which, as a matter of fact, includes nine-tenths of all doctors. Let Mr. Wells help to improve the financial position of doctors by having them paid for their services to the public, and not by a payment of about 1*d.* a week, gross, as he agrees to pay panel doctors. If he agrees to start a medical trades union he will have my active help, and the practical gratitude of all doctors. I am, Sir, yours faithfully,

Liverpool, April 10th, 1916. ROBERT R. RENTOUL.

RIDDING HOUSES OF INSECTS.

A RECENT issue of the *Scientific American Supplement* gives an ingenious method of clearing houses from summer swarms of small insects. Lighted lamps are placed in convenient places, and as the insects gather around the lights they are rapidly and effectively collected and disposed of by holding the nozzle of a vacuum cleaner near the lamp. Presumably the lamp referred to should be an incandescent electric bulb or a flame well protected by a glass chimney, otherwise the suction caused by the cleaner would possibly extinguish the flame.

COMMUNICATIONS not noticed in our present issue will receive attention in our next.

Medical Diary for the ensuing Week.

SOCIETIES.

ROYAL MICROSCOPICAL SOCIETY, 20, Hanover-square, W.

WEDNESDAY.—8 P.M., Prof. B. Moore: Early Stages in the Evolution of Life.—Mr. F. M. Duncan: Studies in Marine Biology.—Mr. J. W. Purkiss: Some Suggestions regarding Visual Efficiency in the Use of the Microscope and other Optical Instruments.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.

MONDAY.—2 P.M., Medical and Surgical Clinics. X Rays. Mr. Gray: Operations. Mr. B. Harman: Diseases of the Eye. Dr. Simson: Diseases of Women.

TUESDAY.—2 P.M., Medical and Surgical Clinics. X Rays. Mr. Addison: Operations. Dr. Banks Davis: Diseases of the Throat, Nose, and Ear. Dr. Pernet: Diseases of the Skin.

WEDNESDAY.—10 A.M., Dr. Saunders: Diseases of Children. Dr. Banks Davis: Operations of the Throat, Nose, and Ear. 2 P.M., Medical and Surgical Clinics. X Rays. Mr. Pardoe: Operations. Dr. Simson: Diseases of Women.

THURSDAY.—2 P.M., Medical and Surgical Clinics. X Rays. Mr. Gray: Operations. Mr. B. Harman: Diseases of the Eye.

SATURDAY.—10 A.M., Dr. Saunders: Diseases of Children. Dr. Banks Davis: Operations of the Throat, Nose, and Ear. Mr. B. Harman: Eye Operations. 2 P.M., Medical and Surgical Clinics. X Rays. Mr. Pardoe: Operations.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY.—Clinics:—10.30 A.M., Surgical Out-patients (Mr. E. Gillespie). 2.30 P.M., Medical Out-patients (Dr. T. R. Whipham); Gynæcological Out-patients (Dr. Banister). 3 P.M., Medical In-patients (Dr. R. M. Leslie).

TUESDAY.—2.30 P.M., Surgical Operations (Mr. Carson). Clinics:—Medical Out-patients (Dr. A. G. Auld); Surgical Out-patients (Mr. Howell Evans); Nose, Throat, and Ear Out-patients (Mr. C. H. Hayton). Radiography (Dr. Metcalfe). 3.30 P.M., Medical In-patients (Dr. A. J. Whiting).

WEDNESDAY.—Clinics:—2.30 P.M., Throat Operations (Mr. C. H. Hayton). Children Out-patients (Dr. T. R. Whipham); Eye Out-patients (Mr. R. P. Brooks); Skin Out-patients (Dr. H. W. Barber). 5.30 P.M., Eye Operations (Mr. R. P. Brooks).

THURSDAY.—2.30 P.M., Gynæcological Operations (Dr. A. E. Giles). Clinics:—Medical Out-patients (Dr. A. J. Whiting); Surgical Out-patients (Mr. Carson); Radiography (Dr. Metcalfe). 3 P.M., Medical In-patients (Dr. R. M. Leslie).

FRIDAY.—2.30 P.M., Surgical Operations (Mr. Howell Evans). Clinics:—Medical Out-patients (Dr. A. G. Auld); Surgical Out-patients (Mr. E. Gillespie); Eye Out-patients (Mr. R. P. Brooks).

THE THROAT HOSPITAL, Golden-square, W.

MONDAY.—5.15 P.M., Special Demonstration of Selected Cases.

THURSDAY.—5.15 P.M., Clinical Lecture.

MANAGER'S NOTICES.

ALTERATION OF INLAND SUBSCRIPTION RATES.

OWING to the alteration in the Inland Newspaper Postal rate, the postage on each copy of THE LANCET will in future be 1*d.*, and sometimes 1½*d.*

The revised Inland Subscription rates are:—

One Year	£1 3 3
Six Months	0 13 8
Three Months	0 7 0

The rates for the Colonies and Abroad (thin paper edition) will be as usual:—

One Year	£1 5 0
Six Months	0 14 0
Three Months	0 7 0

Subscriptions (which may commence at any time) are payable in advance. Cheques and Post Office Orders (crossed "London County and Westminster Bank, Covent Garden Branch") should be made payable to the Manager, Mr. CHARLES GOOD, THE LANCET Offices, 423, Strand, London, W.C.

ADVERTISEMENT RATES.

Books and Publications ... ...

The Milroy Lectures

ON

INFANTILE MORTALITY AND THE RELATIVE PRACTICAL VALUE OF MEASURES DIRECTED TO ITS PREVENTION.

Delivered before the Royal College of Physicians of London

BY S. G. MOORE, M.D. VICT., D.P.H. ENG. CONJ.,

MEDICAL OFFICER OF HEALTH AND LECTURER IN PUBLIC HYGIENE AND SANITATION, TECHNICAL COLLEGE, COUNTY BOROUGH OF HUDDERSFIELD.

LECTURE I.

Delivered on March 9th.

MR. PRESIDENT AND GENTLEMEN,—Rather the importance of the subject proposed for the lectures than any personal merit doubtless led to my election to the Milroy lectureship for 1916. I am content that it should be so, but I will feel still more contented if only I can discharge the duties of the office with some degree of adequacy. I trust that I am duly sensible of the honour attaching to the position, and I tender my best thanks to the Royal College of Physicians of London for the opportunity to make the attempt.

INTRODUCTORY REMARKS.

No human being can contemplate death without sorrow and repugnance, yet these feelings do not extend equally to all deaths. They are influenced by two different kinds of circumstance. On the death of an aged person—one perchance whose span of life has extended to the "sans everything" stage—sadness is mitigated, and we do not experience those feelings of dismay and anguish which burden our souls on the death of one cut off in the bloom of vigorous youth, or in the innocence of infancy or childhood. Our depression is alleviated also when we know that a death has resulted from a cause either inevitable or incurable; at least so far as our present stage of knowledge of these things enables us to judge, a cause which lies beyond the present scope of both preventive and curative medicine, to which, from the practical point of view, these two designations must be applied. Examples of such mortality origins all too readily occur to the mind. How different are our feelings, how much more poignant is our sorrow on the contemplation of a death from a cause we know to have been preventable!

Animated by sentiment alone, it is probable that those who are not immediately concerned are most shocked at the death of some youth cut off in the early promise of active, enthusiastic, earnest, and useful life. Their imaginations are not so readily stirred by the deaths of the very young. But those whose conceptions are founded upon and dominated by reason (as ours should be) will view with the greatest concern the removal of the youngest life—of that being around whom may be centred hopes, aspirations, and plans maternal in their scope. The greatest possibilities appertain to the youngest among the human race. Limitations come to us and accumulate with each advancing year. At 15 or 20 years of age part of life lies already in the past—experience and environment must have set some bounds. To the infant every human possibility lies open.

I have often felt, and said, that from its very nature, from the character of his work, the life of a practitioner of medicine or surgery must be sad—must be tinctured with sombre hues. I know nothing more painful, nothing more depressing, than an understanding contemplation of the subject of infant mortality as it occurs among us to-day. I originally wrote the word "repellent." It might with propriety be applied, yet it does not seem altogether appropriate, for the reason that the experience of the past few years justifies hope, promises reward for intelligently directed work, and also because one may perceive on all hands a growing understanding and an increasing recognition of the fact that here, in work against infantile mortality, is alike a duty and an opportunity.

In the case of the death of an infant from a disease or condition which might have been avoided there is a combination of both those circumstances which enhance the terrors of death—not in old age, nor in mid-life, nor as the result of its own mistakes, ignorance, or misconduct; not from an inevitable cause, nor from one only evitable by great exertion, great skill, at great expense, or the exercise of the highest knowledge, but in the first year of life, almost before the dawn of consciousness; and as the result of ignorance, carelessness, and indifference alike on the part of the parents and the State; far too often, as we will see—in scores of thousands of cases—are these innocent helpless human beings destroyed by agencies which *come to them* from their external environment.

THE INFANT'S RIGHT TO LIVE.

The preventable deaths of infants call for attention from a point of view which, amid more obvious and more practical aspects of the subject, appears either to be lost sight of or else to be taken for granted. Yet from its importance—because it is basic, at the root of the matter—it needs to be plainly set forth and to be constantly borne in mind. A newly born child arrives in the world endowed with certain elemental natural rights, quite apart and distinct from any legal right to property which it may inherit. Because an infant is brought into this life without any volition on its own part these primitive rights come into existence. Every infant holds them directly from those whence it derives its being, that is to say, from its mother and father; and it holds them indirectly from the community, or State into which it is born. The existence of the direct rights of the infant from its immediate parents in no way abrogates its indirect rights from the social organisation as a whole.

What are these rights? All may be comprised in a single statement. The right to a reasonable chance to survive to such an age-period that its own action may influence its destiny, and to a reasonable degree of protection from those external influences which imperil or destroy its life. To furnish an example: Infant deaths from "summer diarrhœa" are practically absent from the returns in winter. They are numerous in summer. Infant deaths from bronchitis and pneumonia are practically absent from the returns in summer. They are numerous in winter. Therefore, in these forms death comes to infants from external conditions. Every infant has the right—a perfect inalienable right, held both from its parents and from the State—to be protected from these and also from all other external causes of death. That is the basic natural right of every child born into this world.

While surely all will agree to the above so far as the parents are concerned, some may doubt that the same is true as regards the community. Because there are criminals in all communities (and for many other reasons) society organises itself. Having done so, how can it stand aside to disclaim this particular responsibility. It is manifestly a criminal thing to permit death to reach a helpless being from its external surroundings and from preventable causes, whether arising through ignorance, or carelessness, or apathy. To me this is a truth which needs to be impressed upon the minds and consciences of all alike, from the lowest to the highest in the land, and particularly upon those who wield power.

I have been led to attempt the above enunciation of the primitive rights of newly born human beings as the result of reflecting upon certain writings and speakings. There are men whose pens and voices hold authority, who express views having a very distinct tendency to militate against work undertaken for the purpose of alleviating the sufferings and preventing the deaths of babies. This may seem strange and incredible. *A priori* it is both. To all who have taken interest in the subject during the last few years, however, this peculiar phenomenon is well known. Moreover, these persons may be divided into two schools—one merely ignorant, prejudiced, careless, and, it may be, parsimonious, and the other trained, learned, scientific.

The former express their thoughts somewhat thus wise: "The poor little devils are born to lives of misery. They will never do any good. Let 'em die." (This is a reproduction of an actual statement by a person holding some authority in the community.) The latter, however, are alike more reprehensible and more dangerous. Their inhuman doctrines are cloaked beneath the guise of science. They proclaim abroad that heredity counts—that environment matters little—acquired characters are not transmitted, and therefore most, if not all, of the labour in this field of endeavour is vain.

Hence the need to proclaim insistently the normal rights of infancy and childhood. Because if these be recognised and conceded, then indeed is vain the clamour both of

those who would "let 'em die" and of those who announce the ultimate futility of efforts directed along lines which are intended to promote the health and general welfare of the infant population.

RETROSPECT.

Your permission will be granted me, I trust, to turn now to a brief retrospect of the Huddersfield special work in this matter. I hope that you will arrive at the conclusion that it is not without interest.

I. *1902–3.*—Scrutiny of the returns of deaths from all causes in the sanitary district with the view to the selection of a disease, or group of diseases, likely to repay special measures for its (or their) prevention.

II. Rejection of tuberculosis, cancer, the common infectious diseases, and alcoholism and its sequelæ for reasons which may be surmised from a consideration of those which led to the selection of infant mortality. These were five in number—namely: 1. The numbers of deaths of infants constituted so large a proportion of the total deaths that any substantial reduction of the infant mortality figure would effect a material reduction of the general death-rate. 2. The causes of deaths of infants in quite a considerable proportion were manifestly preventable. 3. The lives to be saved were at the threshold of existence. 4. When an infant dies, it is through no fault of its own; it appeals from its helplessness and its innocence. 5. The cost promised to be almost negligible. (The rejected subjects were either costly; already dealt with; difficult, on account of the obscurity of their causes, or for other reasons; affected too small a number of persons; or resulted from the actions of the sufferers. The resources of the sanitary authority were not unlimited; selection was necessary.)

December, 1903.—Preliminary report to sanitary authority, reviewing the subject generally.

June, 1904.—Detailed report to sanitary authority, giving a closer analysis of the problems, and setting forth measures already in operation in this connexion in this country, and also in France and Germany, and in particular giving a complete account of the work of Morel de Villiers, which from its excellent provisions and *absolute success* commands an importance to which I propose to direct attention later.

April, 1905.—Final approval by the sanitary authority of a scheme of work against infant mortality based on the above-mentioned reports, and including the voluntary notification of births to the medical officer of health, and the visitation *in their homes* of *all* newly born infants *immediately* after birth by women doctors, followed by voluntary workers. The officials were informed that no inquiry would be made as to how many visits they paid. They were not to be in a hurry, but they were instructed to spare neither time nor effort in the endeavour to be sure before terminating the visit that the mother was instructed fully in the knowledge essential to the welfare of her offspring. Two forms of advice, "short" and "extended," were printed, and were to be left for the information of the mother.

1906.—Parliamentary powers requiring the notification of births to the medical officer of health granted to Huddersfield.

In the following year Parliament passed an adoptive Act enabling all sanitary authorities to require the notification of births to the medical officer of health. This differed from the Huddersfield Act in requiring the notification to be made within 36 hours of the birth, whereas in the Huddersfield clause the period was 48 hours. In 1915 the matter was completed by the passing of an Act which required such notifications to be made to the medical officers of health in every sanitary district in England and Wales.

It appears to be worth while to direct special attention to the period within which the notification must be made. Not within ten days (the normal period of attendance at a birth of a doctor or midwife) but within the minimum practical period—even 48 hours were deemed to be too long. The legislature considered this point and were satisfied of its necessity. That necessity remains, and indicates that the sanitary authorities should take advantage of the opportunity thus afforded to them for the earliest practicable action.

[The lecturer amplified the need. He insisted upon the importance of the following considerations: (*a*) The greatest number of infant deaths occur at the earlier ages. (*b*) The mother's mind is most receptive the earlier after birth advice is given. (*c*) Breast feeding is of the greatest importance. If the visit be delayed the milk may be gone. (*d*) It was under the old régime of advice by the "normal" attendants that the calamitous excess of infant deaths occurred.]

This account would be incomplete if reference were not made to the action of Mr. Benjamin Broadbent. During the period when my reports on this subject were under preparation and consideration he was chairman of the Huddersfield health committee. In November, 1905, he was elected to the mayoralty of the borough. He displayed very great interest in the subject, and helped in some of the translations from the French. On Nov. 10th, 1905, in his mayoral address to the council, he announced that he would make a birthday gift to each child born in his native village of Longwood (which is situated in the borough) during his year of office as mayor, on its attaining its first birthday. To this end he issued a promissory note to the amount of £1 sterling to each child at birth, payable on the infant's first birthday.

This action, from its novelty, attracted an amount of attention which neither Mr. Broadbent, nor myself by any means anticipated. The newspaper press in this country, and also in other English-speaking countries, gave very great prominence to his action in this respect, and I think that I may state, without exaggeration, that the whole movement for the prevention of infant mortality was thereby brought so prominently into the public mind that it received a degree of attention which it might not otherwise have received until much later, and gained an impetus which it has not since lost.

GENERAL REFERENCE.

It is undesirable for two reasons to attempt on this occasion a detailed account of what has come to be recognised as the subject of infant mortality. In the first place, time does not permit. However much one might condense the subject there is ample material for a "summer course" of lectures if all aspects of the subject were dealt with and even only the more direct problems connected with it were taken into account. In the second place, the work has been done so recently, so well, and with such detail that to re-cover the ground now were supererogatory. For several years past medical officers of health, both in special and annual reports, have written on the subject; eminent physicians (including obstetricians) have devoted special attention to this branch of medicine, and have contributed valuable writings to the medical journals, and last, but not least, Government departments have not only investigated and reported specially on the subject, but have given material encouragement in the form of grants to local authorities for the prosecution of actual work in this field.

Let it suffice for me to give the conclusions arrived at in the admirable and compendious reports by Dr. Newsholme, the principal medical officer of the Local Government Board. But before doing so let me refer to the notable fact that successive Presidents of the Board and other Cabinet Ministers have deemed the subject of an importance such as to call for Parliamentary and public attention. And also I would point out that our real governors—the actual arbiters of our national fate (at least I do so regard them); I mean those who direct the daily newspapers—have given prominence to the importance of the subject from the national point of view.

CONCLUSIONS ARRIVED AT IN THE LOCAL GOVERNMENT BOARD'S REPORTS ON INFANT MORTALITY.

From the Thirty-ninth Annual Report.

The Notification of Births Act and the appointment of health visitors have had influence beyond the districts in which the Act has been applied and health visitors have been appointed; for the public conscience has been aroused, and education, moral as well as mental, has rapidly progressed. The continuance of a high infant mortality in a given district involves the continuance of a centre of national weakness. Mortality in the first five years of life is very unequally distributed, the death-rate at these ages in some counties being twice as high as in others.

Excessive mortality in infancy implies excessive mortality in later life. English statistics show that counties having excessive infant death-rates also on the whole have excessive death-rates throughout the first 20 years of life, and that counties having low infant death-rates have low death-rates throughout the first 20 years of life, though the superiority is not so great at the later as at the earlier ages.

There does not appear to be sufficient foundation for the statement that prematurity to an increasing extent is a cause of mortality in the English experience. Every county and most districts whose experience when summarised as a whole show a low infant mortality have within their borders areas in which infant mortality is excessive. The same remark applies to towns which, as a whole have a low infant death-rate.

The subject of child mortality is of national importance. One out of three deaths at all ages occurs under five years of age, one out of five during infancy, and one out of nine total deaths at all ages occurs under three months of age. Infant mortality is the most sensitive index we possess of social welfare and of sanitary administration, especially under urban conditions.

A careful study of the death-rate in England and Wales during the last fifty years at each of the first five years of life leaves it doubtful whether any appreciably greater selection or "weeding out" is exercised by a heavier than by a lighter infant mortality. Any such effect, if it exists, is concealed behind the overwhelming influence exerted by the evil environment to which children are exposed in districts of high infant mortality. It is strictly correct therefore to say that a high infant mortality implies a high prevalence of the conditions which determine national inferiority.

There is no essential causal relation between a high birth-rate and a high rate of infant mortality. The statistics hitherto available for the counties considered in this report do not enable a definite statement to be made as to the influence on infant mortality of the non-domestic employment of mothers.

Infant mortality is always highest in crowded centres of population; but a high infant mortality can be avoided even under conditions of dense aggregation of population. The chief means for a low infant mortality are efficient domestic and municipal sanitation, good housing, and intelligent and painstaking "mothering." Infant mortality is highest in those counties where, under urban conditions of life, filthy privies are permitted, where scavenging is neglected, and where the streets and yards are to a large extent not "made up" or paved. Thus, local sanitary authorities are largely responsible for the continuance of excessive infant mortality, and until they fulfil satisfactorily their elementary tasks efforts in the direction of domestic hygiene can only be partially successful.

Breast feeding is the greatest natural protection against infant mortality. It is not a complete protection, in part because breast-fed infants are often exposed to excessive changes of temperature in air-polluted rooms, and in part because mothers frequently give their breast-fed infants other food of an unsuitable character.

The statistics given in this report emphasise the importance of more detailed investigation of all deaths occurring in infancy as a guide to administrative action. (This has been done in Huddersfield for many years.)

From the Forty-second Annual Report.

The recent fall in the infant mortality figure cannot be attributed merely to favourable climatic conditions. It can be claimed, with high probability, to be the result of improved sanitary and housing conditions, of more efficient municipal and domestic cleanliness, of education in hygiene, of increased sobriety of the population, and of the widespread awakening to the national importance of child mortality, with concentration on efforts of child welfare such as had never previously occurred.

The information as to housing and sanitation is very incomplete. Although the exact causes of excessive infant mortality are complex and vary in different towns, comparison between towns of low and those of high mortality brings out the irresistible conclusion that a very high proportion of the excess of mortality in the less favoured towns can be removed, if the appropriate social and sanitary improvements which are within reach are adopted. It is well known, that after a long series of years during which no appreciable sustained improvement occurred, a great decline in infant mortality has been experienced in recent years.

Geographical position and climatic circumstances have, within the area of England and Wales, only a minor influence on infant mortality, and particular local conditions special to certain limited areas or in certain social classes are responsible to a high degree for the variations which occur in the infant mortality rates.

Infant mortality is higher in urban than in rural areas. The chief apparent exceptions to this rule are large compact villages having urban characteristics, such as the mining villages in the county of Durham. Towns within the same county, sometimes within a few miles of each other, show widely divergent infant mortality rates. Size of town has no definite relationship to excessive infant mortality, this occurring irregularly in towns having a population over and under 50,000.

The infant death-rate for the year 1911, when the prevailing conditions favoured excessive infant mortality, was lower than that of past years with somewhat similar climatic conditions.

A high infant death-rate in a given community implies in general a high death-rate in the next four years of life, while low death-rates at both age-periods are similarly associated.

A consideration of the facts summarised above leads to the conclusion that high rates of infant mortality must depend very largely upon certain local conditions, which may be, and probably are, different for various towns and even for parts of the same town.

The relative importance of the many factors concerned in causing excessive infant and child mortality is difficult to assess; these factors are not identical for all districts. In this part of the present report special stress has been laid upon the factors of defective sanitation and housing, the removal of which is within the control of sanitary authorities. The industrial employment of married women must necessarily involve some neglect of the home, and especially of any young children. Conservancy systems of disposal of excreta are very commonly associated with excessive infant mortality. The smallest incidence of disease, especially of diarrhœal diseases, occurs usually in districts supplied with water-closets. In the history of several towns the conversion of a conservancy into a water-carriage system has been associated with a great reduction of mortality from diarrhœal diseases, whilst in other towns the continuance of conservancy systems has been associated with continued high diarrhœal mortality. Unpaved yards and streets and inefficient scavenging favour excessive infant mortality.

In towns where the general conditions are more satisfactory excessive infant mortality occurs in tenement and other small dwellings, especially where water is distant to fetch and remove, where cleanliness is consequently difficult, and where food cannot be satisfactorily stored.

Such relationship between large families and high infant mortality as is frequently found is in the main indirect, large families being most common among the poorest, who live under conditions unfavourable to child life. Infant mortality is excessive among the poor; it is low among the well-to-do. So far as is known, the proposition is chiefly applicable to those living under the usual conditions of town life.

Poverty is a direct cause of infant mortality where it induces malnutrition of mother or infant or where it implies that the mother cannot give adequate care to the infant. Poverty is also an important indirect cause of infant mortality. Its influence is exercised in the following, among other, ways: (*a*) Poverty is not infrequently associated with ignorance and carelessness. (*b*) With these are commonly associated overcrowding and uncleanliness. (*c*) Alcoholic habits frequently result from living under conditions of poverty, the converse also being true. Poverty, uncleanliness, overcrowding, alcoholic indulgence, and disease are closely inter-related in vicious circles, the starting point leading to excessive infant mortality not always being the same.

The importance of the personal factor in the prevention of infant mortality is very great. The abandonment of breast-feeding without adequate cause is a most important factor of excessive infant mortality.

The object of child-welfare work is to ensure that each parent has within reach accurate counsel as to the hygiene of childhood, and as to the general and domestic conditions necessary for ensuring its maintenance. From the standpoint of medicine this implies such advice as will conduce to the prevention of minor ailments, to their prompt discovery, and to that early treatment which is essential for the prevention of more serious disease.

The experience of organisations which supply food to necessitous expectant mothers appears to show that the condition of the mother before parturition has a definite influence upon her capacity for suckling. This alone is of sufficient importance to call for attention to the condition of the expectant mother.

From the Forty-fourth Annual Report.

A study of the incidence of mortality from childbearing in different counties, and still more of the extreme variations in this mortality in the county boroughs in individual geographical counties, shows that special local factors, other than topographical, must be chiefly concerned in causing local excesses of mortality from childbearing. The majority of the deaths of mothers from childbearing are caused by puerperal fever, hæmorrhage, and convulsions. Most cases of these conditions are well within the range of preventive medicine, including in this the early treatment of illness.

The prevention of early infant mortality is inseparable from that of maternal mortality in childbearing. Excessive mortality of mothers in childbearing means also an excessive proportion of stillborn infants, and an excessive proportion of deaths of infants in the early weeks after live-birth.

The quality and availability of skilled assistance before, during, and after childbirth are probably the most important factors in determining the remarkable and serious differences in respect of mortality from childbearing. The textile towns stand pre-eminent in the toll of life exacted from mothers in childbearing. It is likely that unsatisfactory midwifery bears an important share in producing this result. There must, however, apart from this be a close relationship

between factory work for married women and excessive mortality from childbearing. The experience of Merthyr Tydfil, of Swansea, and of Newport, Mon., shows that other factors may take the place apparently held by occupation in textile factories in producing excessive mortality from childbearing. Although the mortality from childbearing is generally excessive in those parts of England and Wales in which general sanitation is imperfect, in other parts of the country in which similar conditions prevail there is no such excess of mortality.

In order that official action may be taken for reducing maternal mortality and suffering in childbearing, measures must be adopted for ascertaining what cases need help. This condition can be fulfilled by: (*a*) The provision of skilled assistance at maternity centres, which is one of the best means of obtaining such information. (*b*) The notification of births, which provides essential information. (*c*) The notification of puerperal fever when made more effective. Hospital provision for the treatment of puerperal fever is most valuable in itself, as well as in securing more complete notification. (*d*) The collection of the statistics of hospital experience. (*e*) The provision of pathological aids for diagnosis, which will lead to the better diagnosis and treatment of many cases of illness in childbearing. Antenatal work by means of consultations and clinics, together with home visiting, should be organised.

A review of the position as to the distribution of midwives shows that in some areas the supply of midwives is inadequate to the public needs. A review of the work of inspection of midwives shows that this is done to a very varying extent in different counties and county boroughs.

REMARKS ON FOREGOING CONCLUSIONS.

The considered opinions in the Local Government Board's Reports on infant mortality demonstrate the thorough and painstaking manner in which the subject has been investigated by the Board. Of course, they command profound respect. As was inevitable, many of them are not new and many are self-evident. They enunciate clearly and precisely many points calling for attention, they amplify and define much, they fill gaps which were present in our knowledge, they correct erroneous opinions, they give prominence to important deductions calling to be made, they indicate useful lines of action, they recognise difficulties, and generally they are adequate and illuminating. They are so complete that there remain only for elucidation certain questions which can best be answered as the result of local investigation.

Naturally they are of varying importance. Perhaps the greatest service they render lies in pointing out, as they do, that sickness and death in infancy mean sickness and death in later life *pari passu*. The demonstration of the existence of "blots" in good areas, and of the existence side by side of areas of high and of low infant mortalities is of great significance. *Not climate, nor topography, nor municipal sanitation, but the lives, the habits of the mothers in the homes determine the difference.*

I venture to express the opinion that throughout these conclusions too much importance is given to general measures. Because infant mortality is a part only of the general death-rate, and because it is a component thereof which presents special characteristics, *particular* action is needed for its elimination—procedure *immediately* directed against those influences and conditions which are peculiarly inimical to the young. So much in passing; I must recur to this point.

A paragraph in the first report does not lead to the same conclusion as another in the second. They are not irreconcilable. The former tends to show that there is no evidence that the non-domestic employment of mothers is injurious. The latter is to the effect that such employment "must necessarily" do harm. I agree with both of these apparently divergent conclusions. I have reason to know for my own district that the former is well founded (I went into the question in 1908) and I am convinced that the latter must be true But to discuss the matter now would take too long. The influence of the industrial employment of women on family life generally, on childbearing, and on the health and lives of the infants and children has not yet received adequate attention. It should be insisted upon that the family is the unit of the nation. The sum of the families *is* the nation. This social question of female industrial employment is so great and so complex that no individual can investigate it adequately, even in a life-time, yet it needs investigation.

It may be worth while to express the opinion that the explanation of the apparent irreconcilability of these particular conclusions may be the following:—Under satisfactory conditions of family life generally, if in a section of a community the mothers worked all day away from the homes we would be able to show statistically that such employment caused an excessive infant mortality. But the existing conditions are so bad, the infant mortality is so excessive, the margin between the inevitable minimum (of something less than 40 deaths per 1000 births), and the mortality which actually prevails is so great that the effect of the mother's absence from her duties to her offspring is masked by the additional resources commanded by her wages.

I cannot readily accept the dictum that the experience of organisations which supply food to expectant mothers shows that the condition of the mother before parturition has a definite influence upon the capacity for suckling. On the face of it that conclusion appears to be unavoidable. How can an ill-nourished woman so develop during pregnancy that the mammary tissue shall become adequate? It is not to be expected. But we have yet to hear advanced the natural corollary that the uterine tissues of the under-nourished woman fail to increase and to function (except in such cases as come under the proper designation of asthenia). Moreover, we know that the trophic nerves are able to exercise a selective faculty. And also the oft-cited phenomena of the very low infant mortality observed during the Lancashire cotton famine and the siege of Paris increase the difficulty of acceptance of this opinion. True, other factors played a part in Lancashire and in Paris, but it is undoubtedly the case that infants were breast-fed by mothers who had undergone privation during pregnancy to an extreme degree, and who, moreover, were semi-starved during suckling. Nevertheless, all women generally, and all mothers in particular, hold the natural right at the hands of their fathers, husbands, and sons to be well nourished at all times. I merely deprecate this particular statement about nourishment and suckling lest it should form a reason, or an excuse, to withhold from the infant its natural and only proper food.

UNWANTED INFANTS.

There is a painful and difficult phase of the infant mortality question which, however, may not be left out of account. In a certain definite number of cases it is placed beyond doubt by the action of the parents that the infants are unwelcome and unwanted. It is not too much to say that their deaths are desired, perhaps not deliberately and consciously, but the result is the same—these babies die. I could cite many examples, but perhaps the best is afforded by a case of triplets. They arrived in the family of a labourer earning some 25*s*. weekly, where there were already six young children, the eldest still at school. The mother (none will wish to blame her) was overwhelmed by the unexpectedly large accession of family. She and her newly born infants were removed to hospital where they were placed under hygienic conditions as nearly perfect as may be. They had a small ward to themselves. Two experienced nurses were provided, one for day and the other for night duty. The mother had nursed all her other children at the breast. The first untoward incident in the case was the expression of unwillingness on her part to continue that excellent practice. However, she was induced to do so. Then the breast milk commenced to fail, and notwithstanding every effort—hygienic, dietetic, and therapeutic—to promote its secretion, it continued to diminish until at length it failed altogether. The smallest of the infants died after a few days' life, the next after a few weeks' life, and the third after a few months' life. The mother remained in the hospital until within a month of the death of the last survivor. During the whole of the period I never saw her take any interest whatever in the babies. She constantly expressed a desire to go home. She never nursed them after her milk stopped, showed no anxiety about them, nor even grieved at their deaths.

I would like, at this point, to mention a lesson that I learnt from one of the nurses in attendance. When, notwithstanding everything that was being done, the last baby seemed likely to die I said to the nurse, "Whatever is the matter? How is it that nothing seems to answer?" In a manner which showed that she had solved the problem, she replied, "The child has never been 'mothered,' and babies need 'mothering.'" I had frequently heard similar expressions of opinion, but there was something in the circumstances, or perhaps in the tones of the nurse's voice, or in

her manner, which caused me to realise, as I had not formerly done, the importance and significance of what the nurse called "mothering." No doubt robust infants can survive in its absence, but, on the other hand, it is well to recognise the fact that there is an inherent instinct and appetite in the young mammal to huddle and nestle against its mother's body, and to receive warmth and nourishment therefrom. This experience has led me to believe that in all cases these things are necessary for the well-being of infants, and that there may be certain cases where the lack of them determines the balance against the infant, even to the extent of causing its death.

In the case of the triplets I formed the opinion that the death of the first was probably inevitable, but that the other two would have survived had the mother been able to feed them in the natural way. I also came to the conclusion that the lack of milk was the result of the mother's mental condition.

The foregoing is an extreme example of a class. The lamentable fact may not be concealed that from time to time mothers are found who simply will not take the trouble to rear their infants. One recognises the fact with repugnance and expresses it with reluctance and regret. Yet it may not be gainsaid. I propose to show a photograph in the course of the next lecture of a simple form of incubator which we use in appropriate cases. Sometimes the loan is declined, and sometimes after it has been accepted the appliance is not used. Various excuses are made, but the truth is that the motherhood in a very small percentage of women is so feeble that they will not be at the pains involved. Such incidents are not confined to harassed, overworked, underfed women, nor to cases of illegitimates. It cannot be a popular proceeding to point out such facts, but their recognition is necessary to a proper understanding of some of the problems of infant mortality.

SHOCK AND THE SOLDIER.

BY G. ELLIOT SMITH, M.A., M.D. SYDNEY AND ADELAIDE, F.R.C.P. LOND., F.R.S.,
PROFESSOR OF ANATOMY AND DEAN OF THE FACULTY OF MEDICINE IN THE UNIVERSITY OF MANCHESTER.

(*Concluded from p. 817.*)

What Should be Done with Shock Cases after Discharge from Hospital?

IN the treatment of the problem as to what should be done with such patients after their discharge from the special hospitals valuable information can be secured from the German reports, for the concessions made under Prussianism, notoriously devoid of sentimentality, must, at least, be based on necessity. In particular, I shall refer to an address entitled "Die Granatkontusion," and an article on "Hysterie und Kriegsdienst" by Gaupp, published in the *Muenchener Medizinische Wochenschrift* of March 16th, 1915, the latter of which is of more importance in this discussion. In the former, dealing with shell shock, he mentions air-pressure, poisonous gases, mechanical shock, and mental shock as contributory factors in the production of the "general injury," though undoubtedly the most important factor in the production of the class of disturbances with which this communication is specially concerned is *the mental shock of intense fright, especially following on prolonged fatigue and overstrain of the nervous system.* The primary importance of the mental effect in the causation of shock is further stressed by Schuster's observation that bomb explosions are less likely to produce disturbance in a sleeping soldier than in a man awake.

Gaupp gives detailed clinical pictures of these cases, in the great majority of which, though they vary remarkably, the essential underlying condition is remarkably similar. Reference to these descriptions will show that they conform to those published since by our own observers. For the most part the treatment adopted for all these states of shell concussion was suggestion. The prognosis for the acute symptoms is good: the more chronic symptoms, headache, dizziness, weariness, depression, &c., are dependent on the man's physical constitution, on the way in which he is handled, and on his patriotic sense. By an actual instance, he shows the difficulty of successful simulation of insanity, warning the specialist that the presentation of an altogether unusual clinical picture must be received with caution, and an objective report sought for.

In his other article on "Hysteria and War Service," Gaupp mentions that though the nervous condition of the men on the whole has been good, there has been an increase in the number of these cases of pathological excitement and nervous breakdown occurring in soldiers in whose vicinity a shell has exploded. No bodily injury is necessary to bring about these nervous disturbances; terror, often also the psychical shock of seeing dead comrades, is quite sufficient as a causal agent, though the effects produced depend largely on the disposition and temperament of the individual.

There is no evidence in those of Gaupp's writings that I have seen of any attempt to discover the real causes of the disorders with which he deals. He recognises, however, that incorrect treatment often intensifies and maintains this diseased state. Observations made during the treatment of these cases showed that the acute symptoms were generally soon got rid of and the conditions quickly improved. In the less serious cases (headache, &c.) no objective signs of ill-health could be discerned, and the patients, when not professionally observed, appeared bright and fit for anything.

Most significant and important, however, was the observation that, even in some milder cases, any attempt to send the soldier back to the front or the bare mention of this possibility produced a return of the nervous trouble and occasionally of maniacal excitement. In other cases, also, where nervous troubles, uncontrollable in nature and intensity, led to the patient being kept in hospital for many months, it was found that the mental foundation which was a causal factor of these troubles was a more or less conscious anxiety concerning the possibility of a return to the front. "There is no justification[1] for calling every instance of this a case of malingering or simulation. There are men quite capable and morally unassailable whose nervous system is positively unfitted for the hardships and horrors of war. They have enthusiasm and the best of intentions, but this mental inspiration does not continue when the horrors and terrors come. Their inner strength rapidly decreases, and it only requires an acute storm to break on the nervous system (such as bomb explosion or the death of comrades) for their self-control to vanish completely; and automatically their condition changes into what is popularly called hysteria. Feeling within itself that it is no longer master of the situation the exhausted mind 'takes refuge in disease.' At first, as a rule, obvious signs of terror and anxiety manifest themselves (tremor, twitching, &c.); if these are cured there still remain chronic symptoms of hypochondria and despondency. Time, however, has its effect in many of these cases, and the longer the patient is away from the overstrain and terrors of war the more these troubles fade. Only too often, however, an effective residuum remains, due to anxiety about the renewed dangers and horrors of war, and reference to his recall to service may revive the trouble—the recollection of the sight of his dead comrades may suffice to bring on tremor of the whole body." (Gaupp cites the case of an officer.)

(That it would be untrue and unjust to attribute all such manifestations to fear is shown by the fact that a man of unquestioned courage and determination, and apparently devoid of fear, proved and tested in previous wars, may exhibit such symptoms.

A case in point is that of a British soldier, described to me by the medical officer who treated him. The man had suffered from severe shock symptoms and had recovered. In conversation with the medical officer the soldier expressed his willingness and even his anxiety to return to the front, in full knowledge of the fact that the officer's report in that sense would lead to his being sent back to fight. That night the patient was awakened by a terrifying dream, the true significance of which was certainly not adequately appreciated by him. Although he dreamt that he was afraid to go back to the front, apparently he did not realise that he was actually afraid—i.e., that the dream had any meaning. On examination it proved to be a detailed forecast of the imaginary incidents of his return to his regiment and of his attempt to drown himself when ordered to go to France. Here was a man who of his own initiative had asked his doctor to certify him as ready to return; yet in his sleep the train of thought started by the discussion of the possibility

[1] From this point to the end of the section I have included between inverted commas a very free translation—in some cases merely a summary—of Gaupp's remarks concerning the problem of the psychoneuroses as it exists in the German army. My own remarks appear in brackets.

of his return, working subconsciously, had stirred up images of what his return implied, and reinstated emotions of so terrifying a nature that in his dream he preferred suicide rather than face the ordeal again.

Although at the outset of the treatment Gaupp's chief aim, both from patriotic and from scientific considerations, was to bring about the soldier's speedy return to the field, he soon lost confidence in his capacity to do this; and partly from discretion, partly from insight into the nature and causation of these disorders, he changed his views. From discretion, because he considers that hysterical and psychopathic persons are usually inferior soldiers; and he regards it to be the most important duty of the neurologist and psychiatrist to defend his country from the possibility of an accumulation of mental invalids and life-long war-pensioners. Experience teaches that the acute symptoms of war-hysteria are usually curable, and they disappear more easily when anxiety concerning a return to the fighting is removed. These people are quite healthy from the social point of view, and quite capable of earning their own living if one discharges them in this state, so that they may take up their civil trade, or recommends them for a military duty which keeps them away from the front. On the other hand, he finds that traumatic hysteria is not readily cured during war. It tends to persist until the conclusion of peace. But then another difficulty arises in the shape of war-pensions. So long as the war lasts the patient is glad to escape the renewed danger and work again in civil life, for which he is usually capable; but at the end of the war, when work will be difficult to find and a pension lies dazzlingly before him, the impulse to work may fail. Thus, both in order to spare the country great expense, and, by means of work, to free the hysterical permanently from war-hysteria, discharge is often found to be the right measure. Not merely discretion, however, but a full understanding of the nature of hysterical symptoms, led Gaupp to a more cautious attitude; the recognition of the fact already mentioned that in the fight with hysteria the neurologist is in most cases hampered by the fact that the war is still going on. What is the use of patching up a hysterical mind at the back of which fear of the war still slumbers, when the least shock from outside—and in the army there are plenty of these—is sufficient to upset everything again? Often enough the apparently cured person, soon after his return, again breaks down,[2] whereas, even in the most serious cases of hysteria, cure often follows quickly and completely as soon as the patient is certain that he need not return to the front. One is therefore led towards the conclusion that despite the danger which undoubtedly exists of the ominous suggestive effect of such discharges, on the production of complete and semi-simulation all around—a danger which can be averted only by a thorough knowledge of psycho-neuroses and hysteria on the part of the physician—there is nothing else for it but to discharge the men. The situation produced is disconcerting, and any remedy for the puzzling situation, says Gaupp, will be welcome.) "Obviously every method must be used which has been found to be of service in the cure of psychogenic states; and we must not underrate the appeal to patriotism, to the needs of military duty, and the call of comrades."

"But frequently all these influences fail: anxiety, care, and distaste are stronger. The symptoms remain and they become intensified as soon as the words 'fit for duty' are heard. The actual resumption of duty only makes matters worse, because under the stress of war we cannot always expect that those in military command will handle the intensely disturbed soldier with insight and understanding, and with the patience of the expert psychiatrist."

"The secret of handling convalescent psychopathic, and above all hysterical, patients lies in recognising that they must be allowed to work in the right place and in the right way. The military scheme, with its distinction of fitness for field or garrison service and unfitness for duty, does not meet the requirements. Not everybody who cannot be put into the firing line need remain on garrison duty at home, nor is everybody who is qualified for garrison service suited for the fatiguing field training in garrison which is the preliminary stage of field service. Moreover, sentry duty is not always suitable. Unoccupied loafing in barracks is tiresome, even for the sick men themselves. So it often happens that these people are discharged without it being absolutely necessary. In the case of the older men the military organisation is very careful to put their knowledge, powers, and capacity to the most useful service. In the case of the younger troops this happens less often than in the case of those who are relatively fit for service; but a similar procedure is to be strongly recommended in their case also. Many of them—for example, Government servants, such as teachers and clergy, whom the State can spare only with reluctance—might be restored to their positions. They would be much more useful there than in unprofitable oscillation between the front, the convalescent home, and the hospital. Farmers who are not suitable for the front, and are also difficult to utilise in garrison work, because their hysterical symptoms forbid it, can be sent to work at home in the spring and summer, their agricultural knowledge being more valuable to the State than their doubtful military qualities. The case of young shop assistants and workmen, concerning whom there is a question of discharge on account of hysterical symptoms, is different. If their work is in munition factories or serves military purposes in some other way, we need not be much concerned about their discharge to return to such work (naturally under control). If this is not the case, the danger lies in the consideration that after their discharge they will merely increase the number of people without work, so that it is much better to get them a suitable post in military service."

"In this country where the normal activities of the nation are being maintained as well as war work, this consideration hardly applies. The only man who has the necessary information to form an adequate idea of a mental patient's fitness is the medical officer who has studied the individual patient and knows his real condition. No other medical officer or medical board can say whether or not he is fit for work. This officer should be invested with full authority not to send straight back to the front the nervous and hysterical soldier—in whose case a long hospital treatment, for the reasons mentioned above, is of no further use—but to decide how the man should be employed. One must not, however, fall into the error of giving all these semi-useful people clerical or office work to do. In forming a decision as to what each person can do, one must bear in mind his civil occupation, the circumstances of his family, his own feelings and ideas, and his capabilities. If this is done in the right way, hundreds or thousands of nervous hospital inmates whose condition shows no sign of improvement can be employed in ordinary ways."

"A kind of military register for these half-capable nervous men should be compiled. (What is true of these nervous men will be equally so of others—not nervous cases—who are only half capable, so that the question will not be one of small numbers.) Information would be given as to what kind of work can be supplied; and the allotment of nervous patients according to the advice of the medical specialists could then be taken in hand. After a few initial difficulties the organisation should work quite smoothly; in this way work would be obtained from the men so mobilised, the hunt for pensions would be discouraged, and the spur would be applied to the simulator and the exaggerator. Presumably also many healthy people who are fit for field service and garrison duty would be set free, because their present work at home or at the depôts would be taken over by these half-capable people. We should at least try with all the means in our power to keep the men who have once been enlisted for our country's service, so long as serious disease does not make their discharge legally unavoidable. The longer the war lasts the more the number of nervous and hysterical patients will increase; the greater will be the necessity, instead of keeping them as costly inmates of a hospital, of putting their energy to some use in the appropriate part of the military organism."

I shall now turn to the consideration of certain other factors to which many physicians attach great importance in the etiology and treatment of these incipient cases of mental disturbance.

Heredity.

The claim has been made by certain workers that the soldiers who become affected by shock are weaklings or are descended from mentally afflicted or nervous parents. It is,

[2] Dr. Forsyth has explained this danger most forcibly and lucidly in THE LANCET of Dec. 25th, 1915, p. 1403: "It will be admitted that a railway passenger who has suffered a nervous shock in a collision will be little able to undertake railway travelling for some time afterwards; *mutatis mutandis*, this applies to a nerve-shaken soldier, and his return to ordinary duties. But to send the soldier back to the firing line is equivalent to putting the passenger into an express train which, he knows beforehand, is to be wrecked on the journey."

of course, unquestionable that in a large army there must be many soldiers with tainted family histories; and it is probably equally certain that such factors play some part in determining the greater susceptibility of certain men to shock. But it would be a gross misrepresentation of the facts of the case to label all the soldiers who suffer from mental troubles as weaklings. The strongest man when exposed to sufficiently intense and frequent stimuli may become subject to mental derangement. It is quite common to find among the patients suffering from shock senior non-commissioned officers who have been in the army for 15 or 20 years (much of which time has been spent in foreign service under trying circumstances, such, for example, as the South African War), and have stood this severe strain. Such men can hardly be called weaklings.

Even those cases where there is a definite history of a neurotic parent, it would be a mistake hastily to conclude that when the son of such a man or woman becomes a victim of battle-shock it is due to heredity. For when the detailed history of such patients is obtained the fact comes out quite clearly that the social disturbances in the household of such a nervous person may be amply sufficient to inflict severe psychical injuries upon young children.

Further, in many cases the histories themselves clearly and definitely reveal the real etiology of the mental condition, and point to emotional disturbances in children, due to the cruelty of drunken parents, a rankling sense of injustice, a terrifying experience, which might have been an accident or deliberate maltreatment by some human being, or again, to the appalling conditions created in some of these soldiers' homes by nervous and irritable parents, as the real trauma which the "shock" has served to reawaken.

Treatment.

Amongst those whom experience has convinced of the efficacy of psychological treatment for this class of case there are indications of a divergence of opinion in the matter of treatment. One school believes that it is sufficient if the medical man has discovered the real cause of the trouble and explained it to the patient. The other school looks upon the preliminary psychical examination merely as a means of diagnosis, the unveiling of the hidden cause of the trouble; and considers that the treatment should be the laborious and often lengthy process of re-educating the patient, and so restoring to him the proper control of himself. It is of the utmost importance to emphasise the undoubted fact that those who maintain either of these views to the exclusion of the other are committing a grievous and dangerous error, for there is no real line of demarcation between the two schools.

A sensible and intelligent man, once the cause of the trouble has been made clear to him, may be competent to continue to cure himself, or, in other words, to re-educate himself, and completely to get rid of the cause of his undoing. But the duller and stupider man may need a daily demonstration and renewal of confidence before he begins to make any progress. It is precisely analogous to the experience of every teacher of a class of students; the brilliant man will seize hold of a principle at once and learn to apply it without further help, whereas the dull man needs repeated and concrete demonstrations before it sinks into his understanding.

In dealing with soldiers, and this applies with especial force to the regular army, the aspect of many of the cases differs considerably from those of the civilians. Trifling forgetfulness in the civilian would perhaps not be a serious cause of worry, but in the soldier, inured by years of training to strict discipline, forgetfulness even of trivial instructions, or any difficulty in understanding complex orders, is likely to bring down upon his head condign punishment. Such lapses are regarded by the soldier as extremely serious offences, because years of training and discipline have inculcated this idea. When as the result of shock such soldiers are afflicted by even slight forgetfulness, they become worried by it much more than the civilian and exaggerate its importance until it becomes a real terror to them. As the result of their training they regard such phenomena as altogether abnormal; and by a process of rationalising what to them is a novel experience, they are apt to imagine that they are going mad. Such patients often dream about incidents in their army life when they had been forgetful and got into trouble; they become possessed with the haunting fear that they are now likely to get into perpetual difficulties, and are worried by the thought that they are incompetent for the duties to which they have been accustomed, and imagine themselves debarred from all useful work. However, they are easily reassured when the medical attendant explains to them that in ordinary life civilians are frequently subject to such experiences, and that it is only the special circumstances of army life which make such trivial lapses seem serious to them. Not only is the soldier much more scared by such things than the civilian, but it is also a very remarkable phenomenon, and certainly one which came as a surprise, that the neurasthenia of the soldier is apt to be very much more serious than that of the civilian; for when a really brave man is stricken by fear he is more seriously affected by the terror of an experience which not only has a larger element of novelty than in the case of the civilian, but also wounds him more deeply by convincing him that he is lacking in that very quality which is most essential for his professional work.

The Question of Isolation.

There is a considerable divergence of opinion as to whether or not it is proper to treat such patients as exhibit hysterical symptoms by isolation. There can be no doubt that a certain proportion of them, when isolated, make a complete recovery, and that when used with discrimination such a procedure is a very useful therapeutic agent; but it is equally certain that in other cases, and especially in those cases where the whole of the symptoms are determined or influenced by the revival of some painful experience of the past, isolation may not only be ineffective, but even positively injurious. For, by removing the patient from all distracting influences, you throw him upon his own resources, and practically force him to brood over those very memories which are at the root of all his trouble.

It cannot be too strongly emphasised in connexion with this subject that most of the theory[3] and practice of treating hysteria by isolation has been developed in civil practice, and often has been illustrated from cases of well-to-do women living in the lap of luxury. The circumstances of the soldier are entirely different. First, as regards the removal of the patient from the surroundings which caused the breakdown, a thing which has already been done when he was brought back from the trenches into hospital, the isolation of the hysterical soldier can hardly be justified on that score. At the same time, the removal to a military hospital at any rate should obviate all danger of his being pestered by foolish relatives and friends with their mistaken sympathy or excessive attention. And as regards the importance of discipline and routine, the soldier is in a very different position to that of the wealthy society lady, for he has already been subject to such training.

In some instances, however, just as in the civil cases, isolation may have the important effect, by the boredom it induces, of making the patient want to recover and try to recover. But there is the corresponding disadvantage that if you isolate a man and put a special nurse to look after him it is impossible to convince him that his case is not serious. It may, indeed, help him to persuade himself that he is really going insane. As a matter of experience, it is found that very many men cannot stand isolation for long; they feel that they must break out, even if they realise that punishment is certain for doing so. In conversation with patients who are undergoing treatment by isolation they are often perfectly frank about it, and tell the medical officer they will break out at the first opportunity; that the few hours of freedom would more than compensate for the punishment which would come afterwards. Such men, therefore, become a positive nuisance in general hospitals, and whenever possible they should be put into a special hospital.

Without denying, however, that treatment by isolation is effective in a good many cases, there are adequate reasons for regarding it as much less generally appropriate in the case of soldiers than it is in the majority of patients dealt with in civil practice. But it must be apparent that, when the present trouble is due in any considerable measure to the reawakening of emotions linked up with some painful experience in earlier life, isolation is not likely to be effective in many cases, and may be definitely harmful.

[3] The theory of treatment by isolation has been lucidly explained by Mohr in Lewandowsky's Handbuch der Neurologie.

Hypnotic Suggestion.

The question of the possible usefulness of hypnotism in dealing with these cases of shock has been discussed in an interesting way in Colonel Myers's articles in THE LANCET of Jan. 8th, p. 65, and March 18th, 1916, p. 608.

I suppose most physicians who have had any experience of hypnotic suggestion will agree in the main with the mature opinions expressed by Déjerine and Gauckler (pp. 278–283). In patients whose illness is of long duration it is not only inadvisable, on ethical grounds, to resort to hypnotism, but also for the strictly therapeutical reasons that it is not likely really to help in curing the patient, and may even aggravate his illness. "All psychotherapy should first and foremost be addressed to the functions of consciousness, and a method such as hypnotic suggestion which is addressed to the functions of automatism can no longer be practised at the present time" (Déjerine and Gauckler, p. 281). Even suggestion in the waking state, "though in all respects less dangerous than hypnotic suggestion," is subject to the grave objection that in using this method the physician's attention is necessarily directed "to the symptom, and completely neglects the underlying mental [cause]." "By direct suggestion one weakens instead of strengthening the patient's critical power. It does not in any way accustom him to judge his impressions and to recognise the value of his sensations. Here again the attempt to remove the symptoms, or to cure by outside suggestion, only tends to reinforce the patient's auto- and hetero-suggestibility, which form the very source of his symptoms." [4] These opinions concern those cases in which neurasthenic or hysterical symptoms have become definitely established. The problem of dealing with the acute symptoms of shell-shock, such as Colonel Myers has discussed, and perhaps of certain cases of persistent amnesia, does not necessarily fall within the same category.

In the great majority of cases of some considerable duration, and in practically all of those in which the trouble is due to some ante-war worry or emotion, it may be regarded as probable that hypnosis is of no use and in many cases may be positively harmful, for under such circumstances, even with the most favourable conditions, it would result merely in the removing of symptoms; and the removal of one may be followed by the appearance of another, which may even be induced by the process of hypnosis. Moreover, in cases where there is a tendency to the development of a double personality hypnosis may have the effect of emphasising the risk. Further, if the patient has sufficient of his own will-power to enable the process of re-education to be carried out, it is clearly undesirable, both on psychical and ethical grounds, for the doctor to impress his influence from without.

In considering the possibility of the usefulness of hypnotic suggestion it is important to bear in mind that various factors may come into play in impressing an event upon the patient's memory, or in determining the effect of the shock from which the patient is suffering when he arrives in hospital. In the first place there is the vividness or intensity of the stimulus; in the second place, the degree of recency; in the third the frequency of the stimulus; and in the fourth relevancy. By the latter is understood the extent to which a given event appeals to the individual's past experience, and becomes integrated into his own personality.

A patient who has recently received a severe shock, the effects of which alone represent the real trouble, without the disturbance of any antecedent experience, might quite well be relieved by hypnotic suggestion of sleeplessness, pain, or amnesia; and in some cases this removal of the acute symptoms which determine the persistence of the shock effects may lead to complete recovery. A single and sudden wholly irrelevant experience, such as the bursting of a shell, which has no relationship whatever to the patient's past experience, and produces effects by its vividness and its recency, might quite well be neutralised by another kind of wholly irrelevant intrusion, such as hypnotic suggestion. This argument might perhaps be made more intelligible by a homely analogy. A temperate man walking along the street might be thrown temporarily into a condition of faintness or collapse by seeing some ghastly accident, but by taking a "brandy and soda," which to such a man would be a wholly irrelevant experience, the physiological expressions of his emotions might be controlled and he might be able to proceed on his way, and to overcome completely the effects of the transitory experience. But in the case of a man who, for example, had been greatly worried by monetary troubles for a number of years, the "brandy and soda" would not produce anything more than a temporary alleviation of his troubles. The latter illustration represents the chronic psychosis which, as Déjerine has so admirably explained, is quite unsuitable for hypnotic treatment. But the distinguished French neurologist's statements do not seem to apply to the former type of case, due to a vivid recent shock, in the symptomatology of which troubles before the shock play no part. In such cases the results of hypnotic suggestion are often brilliant, if erratic, as is the "brandy and soda cure" for the man who is overcome by a sudden terrible experience in the street.

There are, however, patients who have not sufficient will-power or intelligence to be properly re-educated, in whom, perhaps, a certain amount of suggestion may be of some use, but this class of case is somewhat dubious. I might refer to a case which illustrates the dangers of hypnosis as well as its possible usefulness. It is that of a man all of whose companions were destroyed by the bursting of a shell, and who suffered for months afterwards from complete loss of memory. A medical man hypnotised him, and perhaps with undue tactlessness, brought back the memory of the critical incident at the front, stripped of all the episodes which led up to or followed it. It excited in him the most violent emotions, and he became sick with terror; for the revived incident seemed perfectly real to him, or, as he described it afterwards, "it jumped up against him," and for weeks he was so utterly terrified that he would not go near the doctor. Even though he could not retain the memory of any other recent events the horror of that experience seemed to have made him remember his dread of a particular medical man. But by making use of the information gained during that revival under hypnosis of an incident unknown to anyone but the patient, which his amnesia up till then had kept sealed up, it became possible for another medical officer to bridge the gap between his memory of previous events and the experiences which the patient was known to have had in the military hospitals.

In speaking of the results of hypnotic treatment as being brilliant but erratic, it is important to remember that the same observations apply to suggestion without hypnosis. For instance, the application of electricity to the vocal cords in cases of hysterical aphonia affords an admirable illustration of the treatment by suggestion, even if the method savours of charlatanism. An excellent demonstration of the part which psychical factors play in such cases is afforded by the story of the sailor on the German battle-cruiser *Derfflinger*, recorded by Blässig.[5]

A seaman from the *Derfflinger* was brought into a naval hospital with loss of voice on Dec. 22nd, 1914, and could speak only in a whisper. He said that he had always had good health, with the exception that as a child he had diphtheria, but recovered without tracheotomy or any complication. His voice had always been clear and well under control. At the beginning of December he had a slight cold, which he attributed to sentry duty on deck in very stormy and wet weather. Suddenly he lost his voice, two days after the shelling of Scarborough (Dec. 16th), while he was in the munition chamber of the big guns, and was greatly upset during the firing. After 14 days he recovered his speech. On Feb. 12th, 1915, he returned to hospital with complete loss of voice, immediately after the naval engagement in the North Sea. On Feb. 15th he was treated with electricity, directly applied to the vocal cords, and on March 20th he was discharged with complete recovery of his speech. But on returning to duty, as soon as he went on board his ship his voice was suddenly lost for the third time, and he remained aphonic.

This is clear evidence of the fact that his trauma was psychical. His previous history perhaps contains the clue explaining why, in his case, it was his voice which was affected. The application of the faradic current was suggestion pure and simple.

In emphasising the uselessness or even danger of suggestive therapeutics in most cases that are not quite recent, I have not been referring to that method of suggestion which is involved to greater or less degree in all successful treatment of disease—the process of gaining the patient's confidence and impressing him with the idea that he is going to recover.

[4] Déjerine and Gauckler, p. 232.

[5] Münch. Med. Wochensch., June 15th, 1915, p. 335.

"The conversational attitude, the familar manner of talking things over, the heart-to-heart discussion, where the physician must exert his good sense and feeling, and the patient be willing to be confidential. [This is the method which Déjerine calls "psychotherapy by *persuasion*."] It consists in explaining to the patient the true reasons for his condition, and [for] the different functional manifestations which he presents. It consists, on the other hand, moreover, and you may say almost wholly, in establishing the patient's confidence in himself and awakening the different elements of his personality, capable of becoming the starting-point of the effort which will enable him to regain his self-control. The exact comprehension of phenomena which he presents must be grasped by the patient by means of his own reasoning. ..... The part that the physician plays is to recall, awaken, and direct. He has nothing to do with suggestions."[6]

No one who has not had the experience of guiding mental patients in the way so lucidly expounded by the French physicians can form any adequate conception of the remarkable efficacy of these common-sense methods in restoring to those who are afflicted a normal attitude of mind. It is certainly saving considerable numbers of soldiers from the fate of insanity. These methods are not novel, even if the fuller comprehension of their mode of operation is only dawning upon us now. This point has been admirably expounded by Déjerine and Gauckler, from whose book I must quote once more:—

"May we be permitted to quote a few lines in which Bernardin de St. Pierre has defined, more exactly and better perhaps than we could do, and with a sort of prescience of what is needed, the very rôle that we would like to [see our physicians adopt towards their patients].

I wish that there might be formed in large cities an establishment, somewhat resembling those which charitable physicians and wise jurists have formed in Paris, to remedy the evils both of the body and of one's fortunes; I mean councils for consolation, where an unfortunate, sure of his secret being kept and even of his incognito, might bring up the subject of his troubles. We have, it is true, confessors and preachers to whom the sublime function of offering consolation to the unfortunate seems to be reserved. But the confessors are not always at the disposition of their penitents. As for the preachers, their sermons serve more as nourishment for souls than as a remedy, for they do not preach against boredom, or unhappiness, or scruples or melancholy, or vexation, or even so many other evils which affect the soul. It is not easy to find in a timid and depressed personality the exact point about which he is grieving, and to pour balm into his wounds with the hand of the Samaritan. It is an art known only to sensitive and sympathetic souls.

Oh! if only men who knew the science of grief could give unfortunate people the benefit of their experience and sympathy, many a miserable soul would come to seek from them the consolation which they cannot get from preachers or all the books of philosophy in the world. Often, to comfort the troubles of men, all that is necessary is to find out from what they are suffering."[7]

Déjerine and Gauckler add:—

"One could not express any better, or any more directly, what we never cease to maintain, however lacking in science it may seem at the first—namely, the real therapeutic action of kindness.

Liberated morally, and having regained consciousness of self, and freed in addition from his functional manifestations by the appropriate processes ....., the patient is cured. He is cured from his actual attack. But his mental foundation, his psychological constitution, still remains in the same condition which permitted him under emotional influences to become a neurasthenic. The rôle of the physician is, therefore, not ended. He must still build up his patient's life, still practise prophylaxis, and get the patient into a condition where his character will be established."[8]

General Considerations.

As recently as Jan. 15th, 1916, the *British Medical Journal* was responsible for the statement: "The only hope that our present knowledge of insanity permits us to entertain of appreciably diminishing the number of 'first attacks' lies in diminishing habitual and long enduring drunkenness and in diminishing the incidence of syphilis" (p. 105). This statement would have been sufficiently amazing if it had been made two years ago; but when the hospitals of Europe contain thousands of "first attacks" of insanity, which are definitely *not* due either to alcohol or syphilis, the only conclusion to be drawn from it is that its author must have been asleep since July, 1914, or have become so obsessed by his fixed idea as not to be able to see the plain lessons of the war.

Syphilis, no doubt, is responsible for a very considerable proportion of cases of insanity, and drink *perhaps* for some more; but the incipient forms of mental disturbance which the anxieties and worries of warfare are causing ought to impress upon the attention even of the least intelligent members of the community that such causes are operating both in war and peace, and are responsible for a very large proportion of the cases of insanity. But what is still more important, it is precisely these cases which, if diagnosed in the early stages and treated properly, can be cured. The chief hope of reducing the number of patients in asylums for the insane lies in the recognition of this fact, and acting upon it in the way of providing institutions where such incipient cases of mental disturbance can be treated rationally, and so saved from the fate of being sent into an asylum.

Such measures have been adopted upon an extensive scale in Europe[9] and America, and have met with marked success. In this country our distinctive national obstinacy and the devotion to such catch phrases as "the liberty of the subject"—even when this involves the incarceration of the patient whose liberty to escape treatment and to become insane is the issue so jealously defended—have hitherto proved insuperable obstacles in the way of this tremendous reform. The present war, which has been responsible for destroying so many illusions, has worked many wonders in the domain of medicine. It has forced the authorities to inaugurate the rational and humane treatment of early cases of mental disturbance, which treatment in times of peace they persistently refused even to consider. But if the lessons of the war are to be truly beneficial much more extensive application must be made of these methods,[10] not only for our soldiers now, but also for our civilian population for all time.

[8] Op. cit., pp. 302 and 303.

[9] Major Rows tells us that in the province of Hesse, "by reason of suitable treatment during the early stages of mental illness (the authorities) had been able to postpone for some years the erection of a new asylum in the province." (Jour. Ment. Sci., vol. lviii., 1912, p. 35.)

[10] In an address on the Absence of Proper Facilities for the Treatment of Mental Disorders in their Early Stages (Brit. Med. Jour., Jan. 8th, 1916, p. 41), Dr. Bedford Pierce has recently emphasised the urgency of this reform.

THE PREPARATION AND USE OF CERTAIN AGGLUTINATING SERA.

BY HARRIETTE CHICK, D.Sc.

(With a Note on PREPARATION OF AGGLUTINATING SERUM FOR B. DYSENTERIÆ SHIGA, by E. JEAN DALYELL, M.B.)

(*From the Lister Institute of Preventive Medicine.*)

THE large incidence of intestinal infections among our forces in the Eastern Mediterranean during the summer and autumn of 1915 has led to a continually increasing demand for specific agglutinating sera for purposes of diagnosis. This in itself is proof that the method has proved a trustworthy routine measure for establishing the identity of the organisms isolated from these cases. In these circumstances an adequate supply of specific, high-titre sera is essential, and without making any claim to originality, it may be of use to give a short description of the method employed in this Institute for their preparation, and a few hints as to their use in practice.

Preparation.—After trial of both horses and goats, rabbits have been adopted almost exclusively for the manufacture of these sera. It has been found that they yield the most satisfactory serum, although the quantities obtained are small.

Immunisation is obtained by intravenous injection into the ear-veins of overnight cultures on nutrient agar, washed off with 0·85 per cent. salt solution. In some cases living cultures were alone used during the immunisation; in others these were only employed after a preliminary injection of vaccines heated for about 30 minutes to 56–57° C.; in others again, heated vaccines were used throughout the immunisation. At first a direct count was always made of the number of organisms injected, but after some experience it is possible to gauge the numbers of organisms required for the larger doses as fractions of an agar "slope."

The rabbits selected should be at least 2000 gm. in weight. Each animal under treatment is weighed daily and charts

are kept of its daily weights; these give a useful indication of the general condition. A graduated system of dosage is employed, and the doses succeed each other as rapidly as is permitted by the condition of the animal, the intervals varying from four or five days to seven days or longer if the weight and general health of the rabbit be not sufficiently restored. In this way, with a little experience, the animals can be maintained in good health during immunisation, and it is unusual to lose any during the process. Immediately after an injection the animal needs special care and attention, and extra protection from cold should be provided. A temporary change of diet from cabbage leaves and bran to milk and bread and oats is frequently a great help. Animals which are being immunised with members of the dysentery group show the greatest disturbance after an injection and require the most care.

About seven days (or longer, according to experience) after the final injection a few drops of blood are taken from the rabbit's ear-vein and the serum tested as regards its agglutinating titre for the homologous organism. If the test gives a satisfactory result the animal is bled out immediately, if possible. Urethane (about 5 to 8 c.c. of a 30 per cent. solution) is injected subcutaneously about half an hour previously, and ether is employed at the time of the operation. The animal is bled from the carotid artery under aseptic conditions and the blood is collected in a sterile tube and allowed to clot; the sterile serum is drawn off, usually after standing for two days, and carbolic acid added as a preservative, to a concentration of 0·5 per cent. The yield of serum from a rabbit of 2000 gm. weight is on an average about 40 c.c.

The serum obtained from each rabbit is separately examined, both as regards its agglutinating power for the homologous organism and for the presence of group-agglutinins. The agglutinating serum distributed consists of the pooled sera of several rabbits, each of which has passed satisfactory tests. The mixed batches are re-tested against several cultures of the specific organism and thoroughly examined for group-agglutination, the cultures tested, including, if possible, some recently isolated strains. If time permits, each batch is kept in stock for some months before being issued in order to watch for deterioration.

A number of interesting results have been acquired during the immunisation of large numbers of rabbits. This most interesting fact has been disclosed—viz., that sera of a definite agglutinating titre for the homologous organism may be obtained with some regularity, if immunisation is carried out on standard lines, carefully controlled. This suggests that idiosyncrasy of the rabbit plays a less important part in the process than had been supposed. The individuality of the animal, on the other hand, has a considerable effect on the specificity of the serum, especially in immunisation with members of the dysentery group.

The table below gives details of the procedure found useful in preparing the various sera required; notes are added dealing with the main points of interest special to each group. The figures given in each case express the average titre with the homologous organism and the average degree of specificity which may be expected. These data merely express the average of the results collected up to the present time, and are not to be regarded as final.

Method of testing.—The method adopted for carrying out agglutination tests and determining the titre of sera is one capable of easy reproduction in active service conditions.

The macroscopic method is employed exclusively, and the tubes containing bacterial emulsion and diluted serum are placed in an ordinary incubator at 37° C. The time allowed is two hours in case of the sera of the typhoid group and of cholera, and four hours in case of M. melitensis and the dysentery group. With some dysentery "Shiga" sera the agglutination after four hours cannot be seen with the naked eye, but is distinctly visible with a lens of 10 diameters magnification; in these cases the agglutination titre is marked "microscopic." The agglutination tubes are left at room temperature for about 15 to 30 minutes before being read; they are then left overnight in the laboratory and examined next morning for confirmation. The titres given refer to the appearances at the end of the two or four hours' incubation.

The bacterial emulsions are made from overnight growths on ordinary nutrient agar slopes, washed off with sterile distilled water. This first emulsion is diluted until it contains 2000-3000 million organisms per c.c., a strength which, after preliminary experiments, was found to give a convenient opacity and was adopted as standard. In practice it is attained by diluting the original emulsion until print 2 mm. in width can be clearly read through a narrow test-tube (10–12 mm. diameter) filled with the emulsion. This opacity is, roughly, that obtained when milk is diluted 200 times with water.

As a general rule, fresh living emulsions are used in the test, seeing that the sera are destined for diagnosis of fresh living cultures in practice. Occasionally, however, among members of the typhoid-paratyphoid group it has been found suitable to employ formalised emulsions (containing 0·1 per cent. formalin) in obtaining the titre of the homologous serum.

The serum to be tested is diluted with physiological salt solution (0·85 per cent. NaCl) to a series of strengths ranging from 1 in 62·5 to 1 in 8000 or over. A set of small agglutination tubes is arranged, containing 0·5 c.c. of each of these dilutions and 0·5 c.c. of the emulsion to be tested, so that the final concentration of serum varies from 1 in 125 to 1 in 16,000 or more. The concentration of salt in the final mixtures is 0·42 per cent.; this is found better than full physiological strength in case of organisms (for example, B. paratyphosus B) which have a tendency to self-agglutination, and for this reason the bacterial emulsions are made with distilled water. The macroscopic titre, published with the sera distributed, indicates the highest dilution of the serum giving an agglutination which is readily seen with the naked eye under the stated conditions of the test.

Specificity of sera.—Agglutinating sera prepared with members of the typhoid-paratyphoid group usually show a definite co-agglutination for certain members of the same group, but remain specific as regards the dysentery group. In the same way, the agglutinating sera of the various dysentery types show group-agglutination among each other, but not with members of the typhoid-paratyphoid group. The degree of specificity that is usual with the various sera is shown in the table. In some cases the sera obtained have to be discarded altogether, owing to the presence of group agglutinins which might cause confusion in practice. Even so, it is not always possible to obtain absolute specificity, especially where high-titre sera are desired. It seems as if in the production of a high titre (e.g., 8000–32,000) for the homologous organism, definite group agglutination for members of the same group is also evoked. In general, the degree to which this occurs varies with individual rabbits, and in some cases with the strain employed for immunisation. Numerous examples are to be found below in the table. An experienced worker will often detect group-agglutination by its incompleteness and the slowness with which it takes place. Moreover, error is avoidable if for diagnostic purposes the sera are employed in an appropriately high dilution, and this procedure has the additional advantage of economy. It is now the custom in this Institute to indicate, with all sera issued, what dilution is recommended for diagnosis.

If it is the practice in any pathological laboratory to make up a certain fixed dilution of agglutinating sera for routine diagnosis, this dilution should in each case have reference to the titre of the sample of serum used, and while low enough to include the less agglutinable strains of the homologous organisms should be sufficiently high to avoid the confusion of group-agglutination. In any case, it is not advisable to rely upon the agglutination test as a sole means of diagnosis, but the organisms isolated should always, where possible, be submitted to cultural tests in addition.

In this Institute, at the present time, agglutinating sera are tested for specificity against fresh living emulsions of other members of the intestinal groups of organisms. In the past formalised emulsions were sometimes used. It has been shown,[1] however, that the presence of formalin in emulsions inhibits group-agglutination; in these circumstances it has seemed advisable to make all specificity tests with fresh emulsions, so that the tests may be as rigorous as possible.

Typhoid-paratyphoid group: B. typhosus, B. paratyphosus A, B. paratyphosus B, B. enteritidis Gärtner.—Agglutinating sera for the members of this group are prepared without difficulty and a high titre is readily obtained. B. paratyphosus B is the most toxic for rabbits and, in immunising, it is necessary to start with small doses and to proceed with some caution. Still, if the animals are treated with care there is no difficulty in bringing them to the end of the immunisation in good health. With B. typhosus, B. paratyphosus A, and B. enteritidis Gärtner there is usually little difficulty or danger.

The character of the agglutination is also very satisfactory; it takes place rapidly and the aggregated bacteria give a coarse and flocculent deposit. This is in marked

[1] See Dreyer, Proceedings of the Royal Society of Medicine, Medical Section, vol. ix., 1915, p. 11.

Table giving Preparation and Properties of Agglutinating Sera of the Different Pathogenic Intestinal Organisms.

Note.—(The doses are arranged for rabbits of approximately 2000 gm. weight.) The numbers expressing titre refer to the highest dilution in which macroscopic agglutination is clearly visible to the naked eye under the conditions of the test.
The specificity tests in every case were made with the serum obtained at the final bleeding.

* Considered unsuitable for distribution.

contrast to the reaction in the dysentery group, where the agglutination is fine and granular and takes place much more slowly.

The great drawback is the presence of co-agglutination with other members of the group. It may be noted that these cross agglutinations do not always involve members which are most closely related culturally. The most striking group-agglutination encountered is that of typhoid sera for B. enteritidis Gärtner.[1] This property, which varies with individual rabbits, seems also to depend upon the strain of B. typhosus used for immunisation. A considerable amount of high titre typhoid serum has been rejected on this account and search is being made with some success for a strain of B. typhosus which will produce a serum more specific in this respect.

B. paratyphosus B sera do not commonly agglutinate B. enteriditis Gärtner to any extent, as might have been expected, but Gärtner sera have been found to agglutinate emulsions of B. paratyphosus B.

The agglutinating sera of this group are very stable. They have been found to retain their titre at full strength during the time they have been under observation. In some cases these periods have extended to 12 months and the serum has remained stable, whether in the pure or diluted condition and whether kept in the laboratory or under conditions of uniform low temperature.

Dysentery group: B. dysenteriæ "Y" and "Flexner."—A marked group-agglutination for B. dysenteriæ Shiga is usually present in "Y" sera; on one occasion a titre of 2000 was noticed when the titre for the homologous organism was only 8000. In this respect great variation has been noticed in different individual rabbits. The limit of agglutination titre for B. dysenteriæ Shiga permitted in "Y" serum has been about 500, and the sera of rabbits immunised with "Y" have occasionally to be discarded owing to this limit being exceeded. Sera prepared with B. dysenteriæ "Y" (original strain of Hiss and Russell) usually agglutinate strains of "Flexner" to a degree commensurate with the homologous strain, but sera prepared with "Flexner" have been found much more specific (see the table above). The strains of "Flexner" and "Y" have been stock strains in the Lister Institute for some years; the "Y" has acquired the property of fermenting maltose, and both cultures now ferment saccharose slowly. In this latter property they show a leaning towards the type B. dysenteriæ "Strong." The relation between these three types of dysentery is at present somewhat uncertain. The "Strong" type possesses the greatest fermentative activity, but individuals of the "Flexner" and "Y" type show an inclination to acquire some of the properties considered typical of "Strong," such as fermentation of sorbite, saccharose, &c. As regards serological characteristics, the relation between dysentery "Y" and dysentery "Flexner" must be regarded as a very close one, and, when the similarity in cultural characters is also taken into account, it would seem unnecessary at this stage to attempt any systematic separation of these two types.

It has not been possible to prepare sera with the "Strong" type of dysentery as an authentic culture, showing typical culture reactions, could not be obtained.

B. dysenteriæ "Shiga." The preparation of agglutinating serum for B. dysenteriæ "Shiga" presents considerable difficulty, and the methods used in this Institute have not yielded the consistent results obtained with other organisms. Further experiments are now in progress, and it is hoped that a satisfactory method for obtaining uniform results will shortly be evolved. Up to the present time preliminary doses of about 50 million organisms, followed nine or ten days later by 100 millions, both vaccines killed by heat, have been injected subcutaneously. This has been followed by intravenous doses, gradually increasing in amount until about 8000-10,000 millions, or more, living bacilli could be given. The first subcutaneous doses are the most dangerous, and it has been unusual to bring more than 20 per cent. of all rabbits employed safely through the immunisation process, and there is no certainty that in the serum of the survivors a high agglutination titre will develop. Moreover, after removal from the rabbit, the serum frequently deteriorates rapidly during the two or three months following. Owing to these facts, the available supply of "Shiga" agglutinating serum has remained very limited in amount and the supply issued has, in the main, depended on a few chance successes among a large number of rabbits used.

The serum produced by immunising rabbits with B. dysenteriæ "Shiga" varies considerably with regard to specificity. As has been stated above, the serum never causes any significant agglutination with members of the typhoid-paratyphoid group, but "Shiga" serum of a titre equal to about 2000-4000 commonly gives reaction with dysentery "Flexner" or "Y" in dilutions up to 1 in 250. About 50 per cent. of all the serum obtained has exceeded this limit and has been rejected; the sera selected for distribution have usually been of low titre (1000-2000), but definitely specific for B. dysenteriæ "Shiga."

In case of dysentery sera, deterioration has frequently been noticed on keeping, more noticeably in case of "Shiga" serum. Experiments are in progress to ascertain whether this may not be due to the presence of the 0·5 per cent. phenol as preservative. Methods of drying these sera are also under investigation. These appear to be promising and it is hoped that dry preparations may prove stable and especially suitable for tropical climates.

V. choleræ.—In the case of cholera, certain cultures produce sera which are limited in agglutination for other strains of cholera. The practice in this Institute has been, therefore, to immunise several rabbits with single strains, afterwards pooling the sera. The following strains (for two of which I am indebted to the kindness of Dr. Freeman) were selected with a view to including as wide a variety as possible: (1) "27," received from Russia, November, 1909; (2) "Singapore," from Straits Settlements; (3) "Freeman, 31," Russia, isolated in the autumn of 1914; (4) "Kucera," Hungarian epidemic, 1913; (5) "Liston," isolated in Bombay, March, 1915.

Cholera-agglutinating sera have proved very stable.

M. melitensis.—It has been found difficult to obtain high-titre agglutinating serum with M. paramelitensis (see also Bassett-Smith, *Journal of the Royal Army Medical Corps*, 1915, vol. xxiv., p. 431), nor does there appear to be any advantage in prolonging the immunisation beyond the three doses given in the table. The sera obtained always failed to agglutinate emulsions of M. melitensis at a dilution of 1 in 125, but the corresponding M. melitensis sera, of considerably higher titre, frequently agglutinated M. paramelitensis at about 1 in 500. The vaccines used in immunisation were made from 48 hours' cultures on glucose agar.

NOTE ON PREPARATION OF AGGLUTINATING SERUM FOR B. DYSENTERIÆ SHIGA.

BY E. J. DALYELL, M.B.

April 4th, 1916.

Since the preceding notes were written a satisfactory method for the preparation of agglutinating serum for B. dysenteriæ Shiga has been established. Preliminary work showed that repeated subcutaneous doses of vaccine produced only a low agglutinating titre for B. dysenteriæ Shiga in the serum of rabbits, and that a single intravenous dose was much more effective. Further, initial subcutaneous doses of 50 million bacteria caused a mortality of 50 per cent., which was not appreciably diminished by washing or sensitising the organisms. When intravenous doses were used, 20 million bacteria could be injected with comparatively little risk to the animal, and the immunisation could be completed in about one month by a series of graded intravenous doses at intervals of about seven days. It was found dangerous to employ a larger first dose than 20 million organisms, and this strength was estimated by careful counting. There is no evidence that toxicity is lessened by heating the emulsion, and all doses after the first were unheated.

Various strains of B. dysenteriæ Shiga showed considerable differences as regards toxicity and immunising power. A recently isolated strain (Wynne) of low toxicity was finally selected, and proved very effective as an immunising agent.

After each dose the animal loses weight and generally refuses food; in severe cases paralysis of the limbs and diarrhœa are observed. The animal is kept warm and fed with milk, administered with a tube if necessary, and often recovers completely in three to four days. The daily weight chart usually shows that it is safe to give the next dose

[1] This phenomenon is interesting in connexion with an observation which has been made repeatedly (most recently by Dawson, Brit. Med. Jour., July 24th, 1915) that the sera of patients suffering from typhoid fever agglutinate B. enteritidis Gärtner.

seven days after the preceding one. After four or five doses the maximum titre is reached, and for B. dysenteriæ Shiga this appears to be about 2000 in rabbit serum; a higher titre (of 4000) is rarely observed, and in some instances it is impossible to induce better titre than 1000. When a good titre of 2000 is produced in the serum it is generally useless to try and improve this by additional vaccination, and the rabbit should be bled out. Several rabbits kept under observation for two or three months and repeatedly inoculated with B. dysenteriæ Shiga have gradually lost their agglutinating power for this organism, and it has been impossible to restore it.

Specificity.—The method of rapid immunisation by intravenous doses produces a more specific agglutinating serum than the previous, more gradual, method with preliminary subcutaneous injections. The production of co-agglutinins for B. dysenteriæ Flexner and B. dysenteriæ Y was not found to depend on the strain of Shiga used for immunisation, but varied with individual rabbits, and it is at present unexplained. In a few cases no co-agglutinins were

* According to condition.

detected, but in the majority of cases a titre of 250 for B. dysenteriæ Flexner and 125 for B. dysenteriæ Y was developed. In a certain number of rabbits, after prolonged dosage with B. dysenteriæ Shiga, the titre for B. dysenteriæ Flexner and B. dysenteriæ Y reached 500 or 1000; such sera were rejected.

The normal serum of rabbits often shows some degree of agglutination for B. dysenteriæ Flexner or B. dysenteriæ Y, and it is advisable that examination of serum should be made before commencing immunisation with B. dysenteriæ Shiga in order to reject all animals that possess agglutinating properties for the mannite-fermenting dysentery organisms.

QUEEN'S HOSPITAL FOR CHILDREN, HACKNEY-ROAD, N.E.—The annual concert given by the Queen's Hospital Aid Society in support of the funds of this institution was held on April 13th at Shoreditch Town Hall. The concert was very successful, and there was a large attendance. The songs rendered by, amongst others, Miss Edith Evans, Miss Marion Beeley, Mr. John Booth, and Mr. Norman Allin were much appreciated. The funds of the institution have benefited in previous years through these concerts to the extent of £4955. The Queen's Hospital for Children has done, and does, excellent work in the battle with disease and physical defect amongst our young population. For many years it has made organised efforts, in coöperation with schools for mothers and similar institutions, to reduce the infant mortality of the surrounding districts; and owing to the provision necessarily made in London for military cases, it is now called upon to deal with a larger number of children than ever before. The Lord Mayor has come forward to help the hospital by holding a Mansion House meeting in support of an appeal for £5000. The meeting will take place at the Mansion House on Thursday, May 11th, at 3.30 P.M.

INTRAMINE: A NEW ANTISYPHILITIC REMEDY.

BY HAROLD SPENCE, B.A., M.D., C.M.,
RESIDENT SURGICAL OFFICER, LONDON MALE LOCK HOSPITAL.

SOME months ago Mr. J. E. R. McDonagh handed me samples of several synthetic preparations of sulphur which he had prepared, with instructions to employ them in the treatment of cases of syphilis with a view to determining their value. It was soon apparent that di-ortho-amino-thio-benzene, otherwise known as "intramine," was the most valuable of these, and I desire in this paper to report some clinical results following its use in a series of 65 cases of syphilis.

Origin of intramine.—In THE LANCET of Jan. 29th Mr. McDonagh alludes to researches in which he has been for some time engaged, designed to explain the action of arsenical compounds in syphilis and to clear up as well the empiricism of the Wassermann reaction; in the course of which investigations the possibility of new antisyphilitic remedies was suggested. Pending a full report of this work shortly to be made by him, I shall endeavour to give a brief and non-technical summary of his views as there expressed. He regards the action of salvarsan and similar drugs as organotropic rather than parasitotropic, as stated by Ehrlich. The latter believed that the arsenic became attached to, what he termed, chemoceptors in the protoplasm of the parasites, thus in suitable dosage effecting their destruction without injury to the host. It was found in practice, however, that relapses even after repeated injections of salvarsan and the occurrence of nervous complications were by no means infrequent, except perhaps in the earliest cases, and conservative treatment required the exhibition of mercury as well, for a longer or shorter period. This failure of salvarsan to cure has been variously explained. By some authorities it has been ascribed to the escape of certain spirochætæ, which have in some manner become inaccessible to the remedy; whilst by others it is believed that the spirochæta pallida is merely a phase of the organism responsible for syphilis. Whatever the correct explanation may be, the one fact upon which there is general agreement is that salvarsan does not always eradicate syphilis.

Chemistry of intramine.—Mr. McDonagh discards the theory of chemoceptors and considers the rôle of arsenic as essentially that of a catalyst, its action being greatly to increase the protective powers of the host. These last are described as of a chemico-physical nature and to consist in a process of adsorption between the lipoid-globulin molecules of the serum and plasma cells and those of the parasites, involving the destruction of the latter. For this consummation the presence of active oxygen is necessary, and this is supplied in the body chiefly through the action of a peroxidase upon a peroxide. The action of arsenic in a preparation of the salvarsan type is that of a peroxidase, with the result that the natural defences of the body for the time are fortified or magnified greatly. That its action is not parasitotropic is further indicated by the fact that experiments with other metals, notably with preparations of aluminium and iron, reveal that even more powerful drugs of this character can be prepared, these possessing the added advantage of being non-toxic.

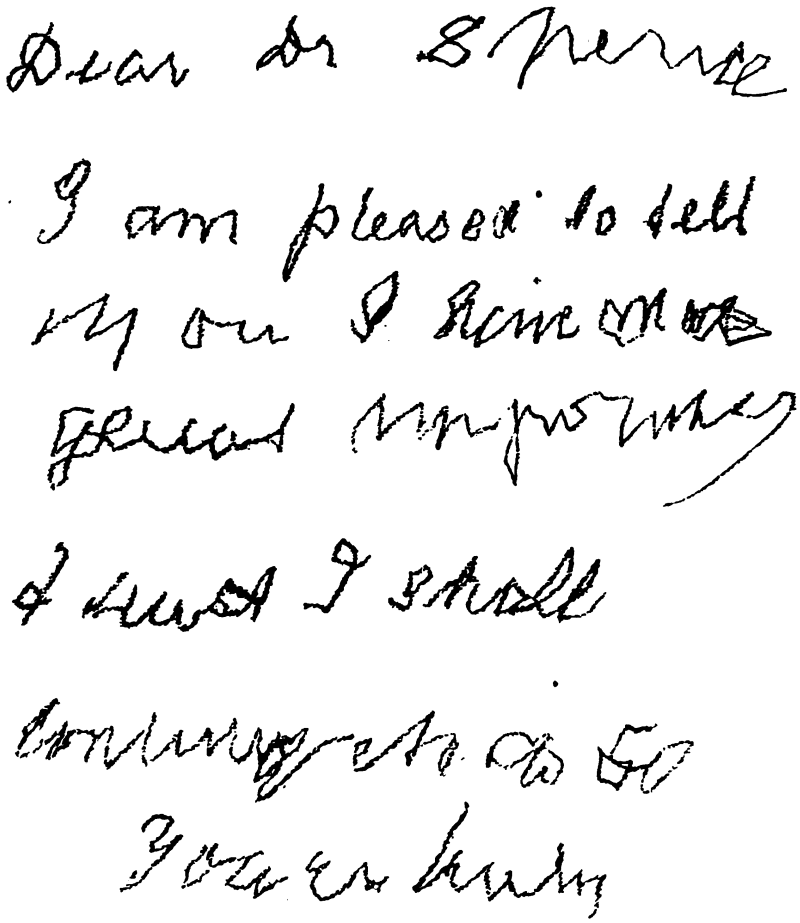
As syphilis becomes more chronic, the ability of the host to form active oxygen directly is lessened, and in consequence he is obliged to form most of it indirectly, through the action of a perhydridase, or in other words, by means of reduction. It was found that while certain metals, of suitable valency and atomic weight, acted as peroxidases, the perhydridases were non-metallic, and it was sought to produce a drug which would have the same activity in late cases of syphilis as is possessed by aluminium, iron, and arsenic in the earlier ones. Many compounds of readily adsorbed non-metals were synthesised, of which the most successful in practice, as already indicated, was intramine, sulphur appearing to be the catalyst. After having been absorbed the sulphur appears to act as a disulphide, the action of the disulphide being to produce active hydrogen and the peroxide required to furnish active oxygen.

Properties and administration. — Di-ortho-amino-thiobenzene is a mustard-yellow crystalline substance, soluble in alcohol, ether, and acetone, but insoluble in water. For intramuscular administration, the only manner in which it is

at present employed, it is suspended in oil in the proportion of 1 gramme in 10 cubic centimetres. This readily passes through an ordinary intramuscular needle and is administered precisely as grey oil is given, the needle-hole being preferably sealed with collodion to prevent leakage and the possible supervention of a slight dermatitis. Up to 12 grammes have been given, but full therapeutic effect is obtained with 1 or 2 grammes, repeated in a few days if required. Local pain after administration is a variable symptom, some patients complaining of severe and persistent pain, while others, and particularly those accustomed to intramuscular injections of mercury, may experience nothing more than slight stiffness. There seems no objection, however, to the addition of a local anæsthetic, particularly with female or nervous patients, and I prefer quinine and urea hydrochlorid, the anæsthesia from which lasts several days. Injections are best made at the point midway between the anterior superior spine of the ilium and the upper end of the natal cleft, the needle being directed forward, inward and slightly upwards. From 24 to 48 hours after injection a rise of temperature and some malaise may be looked for, but rarely does the thermometer reading pass 103° F. The induration at the site of injection disappears in a few days and with ordinary aseptic care there should be no sloughing, and in my own cases there has been none.

Reports of Cases Treated.

It has been said that the metals are indicated in the treatment of early manifestations of syphilis, the field of the non-metallic remedy being the later stages of the disease where metallic compounds alone are less useful. Here 1 gramme of intramine should be injected intramuscularly, followed on the third or fourth day, when any immediate reaction will have subsided, by a metallic preparation intravenously. My experience has been, however, that not infrequently the lesion has disappeared so rapidly that it was healed or nearly so before the arsenical or other preparation could be given. Most of the later cases summarised below will be seen to be of this category. In primary syphilis I have found intramine little effective. Given after a metallic preparation it may occasionally accelerate the disappearance of a secondary papular rash and the induration of a large sore of the Hunterian type. It seems also to influence favourably superadded ulcerative conditions.



CASES 1, 2, and 3.—Three patients with primary sore treated only with intramine, a clean dressing being applied locally. One developed secondaries while under treatment, and none was benefited appreciably in two weeks.

CASE 4.—A sailor aged 31. This was one of the first patients treated with intramine. When admitted he had a profuse small-pattern maculo-papular rash, a sore on the penis with secondary mixed infection, and oral lesions. Intramine 0·45 grm. was given every fifth day for five doses. The infection about the sore was at once favourably influenced without other treatment, but while the papules on the trunk retrogressed steadily the improvement in this respect was not remarkable. Papules on the buttocks and thighs and upon the flexor surfaces of the forearms were more resistant and were present at the end of four weeks.

CASE 5.—A man aged 27. This patient had a large tense indurative œdema of the penis, concealed sore, and a maculo-papular rash of ten days' duration. Intramine 4 grm. was given, but no improvement appearing within a week other treatment was instituted.

CASE 6.—A man aged 25. A case of secondary syphilis and gonorrhœa, the first acquired three months previously, the other three weeks. He had also had adenitis of the right groin, where upon admission to the wards was an irregular sluggish ulcer of the size of a half-crown. The latter had been treated with local applications and ionisation without result. First he was given galyl, 35 cgrm., intravenously, and two days later 2 grm. of intramine, a sterile dressing being applied to the exulcerated area. One week later the ulcer was cleaner and smaller. The galyl was repeated twice at weekly intervals and the intramine at the end of a month after admission, the ulcer being then nearly healed. Three days later it had entirely closed.

When we pass, however, the early secondary stage intramine is capable of producing results which are often surprising and which, after a considerable experience in the use of arsenical preparations, I am sure they will not generally produce. I refer particularly to recurrent lesions, early and late, gummatous conditions, interstitial fibrotic conditions, and such troublesome complications as painful fissuring of the tongue, these constituting over two-thirds of the cases I have treated with intramine, either alone or in combination with galyl.

Facsimile of letter written by paretic patient, described as Case 13.

CASE 7.—A man aged 70. This patient I exhibited among others at a recent meeting of the Dermatological Section of the Royal Society of Medicine. He contracted syphilis in 1866 and had complained of a bad tongue for 25 years. He first came to the hospital 18 months ago, when he had two intravenous injections of "606," which caused little or no improvement in the tongue condition. The salvarsan was followed by three courses of mercurial injections and iodides, which likewise produced no improvement. On Nov. 6th, 1915, the patient was given 1 grm. of intramine. At this time he exhibited an ulcer, the size of a sixpence, on the dorsum of the tongue, with two fissures running laterally from it. Posterior to the ulcer was a wart about the size of a small cherry. The movements of the tongue were restricted and the patient suffered considerable pain and discomfort. On the third day after the intramine the tongue began to improve, and when he was seen again in a fortnight the ulcer had closed, the fissures had disappeared, and the wart was considerably smaller. Two months later the tongue was soft and perfectly mobile, the wart nearly disappeared, and the patient suffered no pain or discomfort—as the patient said: "The tongue has never been so well for years."

CASE 8.—A man aged 27. Contracted syphilis about May 1st, 1915, chancre appearing three weeks later, for which a chemist prescribed a lotion and a few pills. When first seen, Oct. 23rd, there was an erosion at the site of a healed sore, a faint disappearing rash, half a dozen radiating painful fissures of the dorsum of the tongue, tonsillar ulceration, and a dull red scaly inflammation of the chin. I injected 2 grm. of intramine, and in three days the chin was paler and less scaly. The tongue, the most troublesome lesion, and that which prompted him to seek advice, was improved, and upon his next visit, four days later, the fissures had closed. There was some improvement in the condition of the tonsils and pharynx, but the addition of local measures was required to clear up these symptoms fully.

CASE 9.—A sailor aged 32. He had contracted syphilis four years previously, and secondaries being slight had received no treatment whatever. When first seen there was a scooped-out tertiary ulceration of the glans penis 1·7 cm. in diameter and 0·5 cm. in greatest depth. One injection of intramine, 1·5 grm., was given, with the result that almost immediately the process was arrested and within a week there remained only a healed depression.

CASE 10.—A man aged 28. This patient contracted syphilis early in May, 1915, and attended the hospital for the first time on June 12th, when intramuscular injections of mercury were commenced. After the fifth weekly injection he discontinued treatment, the sore having then closed and a slight roseola being also gone. Four months later he returned, exhibiting a superficial recurrent syphilitic ulceration of the under surface of the skin of the penis, 6 cm. in length and 0·3 to 0·5 cm. in width, and some sluggish inflammation of the skin of the scrotum adjacent. Three grammes of intramine were given. Forty-eight hours later the ulceration had healed, one of the most remarkable results that I have ever seen. In the intervening day the patient seems to have had a fairly marked febrile reaction.

CASE 11.—A man aged 45. Acquired syphilis 13 years ago, following which he appears to have had very inadequate treatment with mercury spread over five years. Upon examination I found an irregular gummatous lesion of the under surface of the penis, somewhat less than a shilling in size, with a moist and sloughing crater-like base, the ulceration in its progress having opened the lower wall of the urethra at the meatus. Three grammes of intramine were given, and upon his next visit to the hospital a fortnight later the lesion was healed and its area shallower and smaller.

CASE 12.—A man aged 21. When first he attended the out-patient department a healed sore was found, a disappearing rash, and painful fissuring of the tongue, with mucous membrane lesions. Six full doses of galyl were given at weekly intervals and all symptoms disappeared with the exception of the tongue affection, which failed also to respond to routine treatment and local applications. One gramme of intramine was finally administered, and in two weeks the fissures had closed.

Syphilis of the nervous system.—Quite recently I have been prompted to test the efficacy of intramine in the treatment of syphilis of the nervous system, my cases thus far being limited to two of tabes dorsalis, one of Erb's syphilitic spastic paraplegia, and one of general paralysis of the insane. Regarding the first three, I have no objective improvement to report. One of the ataxic patients states that he can now "feel the ground," and is much encouraged in consequence. The progress of the patient with general paralysis of the insane has been sufficiently interesting to merit a detailed reference.

CASE 13.—A man aged 39. First symptoms were noticed in December, 1914, when he became irritable and uncertain in temper, this being quite unlike his previous invariable good nature. Thenceforward his wife, the informant, observed a progressive change in his disposition: he was always tired and found increasing difficulty in concentrating his attention upon any task; his handwriting became shaky and his gait uncertain, his condition at the end of six months being such that he was obliged to relinquish his work. He was then referred to a psychiatrist, who diagnosed general paralysis of the insane, a diagnosis subsequently confirmed by a second consultant. After a slight transient improvement, on or about August 10th, 1915, there occurred a paralysis of the right upper extremity, and interference with speech, which had now become definitely tremulous and hesitating. He became steadily worse as the weeks passed, displayed marked defects of attention, interest was retarded, and he was frequently confused. Upon admission to the hospital, on Jan. 14th, 1916, he presented a typical picture of paresis of the depressed type. He was disoriented and retarded, any replies finally secured being hesitating, tremulous, and incoherent. He was poorly nourished, filthy, and indecent in habits, occasionally resistive, and required every nursing care. Deep reflexes were minus, pupils unequal and only very sluggishly responsive to light. On the day following admission he had a slight general convulsion. Three grammes of intramine were given, repeated in one week. Two days following the second injection there was a recognisable and rather sudden improvement; he answered more readily and more accurately, and was cleaner in habits. Three days thereafter he was able to be up in a chair and partially dressed for two hours, was correct in habits and conduct, recognised the call to stool, and returned coherent answers to questions with little retardation. On the following day, however, he relapsed, and was mildly disturbed throughout the night. Again he received intramine, 3 grm. (Jan. 30th), followed in five days by galyl, 40 cgrm. Two days subsequently he was better than at any time, conversing pleasantly with his wife and the attendants, and evincing a good realisation of his circumstances. The intramine was repeated on Feb. 10th, 1 grm., and the galyl three days later. The letter reproduced (see figure) he wrote and composed himself, at my request, on Feb. 14th, or one month after admission: his first attempt to write in some months. At this time he was sitting up several hours daily, walked with the assistance of his nurse to the toilet rooms, and took a few steps without help, although unsteadily.

In non-syphilitic cases.—Intramine has been given in a few cases of lupus vulgaris, where it has been useful in rapidly clearing-up ulcerated areas, due to caustic treatment or otherwise. I have seen one case of lupus exuberans in the service of Dr. H. G. Adamson at St. Bartholomew's Hospital, where not only was the ulcerated part quickly healed but the whole lesion became paler in colour. It seems also to be of some value in the treatment of chronic infective or degenerative processes, non-syphilitic in character, such as troublesome leg ulcers. Further investigation will define its full usefulness, and its limitations.

Summary and Conclusions.

The arsenic in salvarsan and similar remedies is not parasitotropic, but acts as a catalyst, multiplying the protective power of the host. This is of a chemico-physical nature, and consists in a process of adsorption between the lipoid-globulin molecules of the serum and plasma cells and those of the parasites. For its consummation the presence of active oxygen is necessary; supplied in the body chiefly through the action of a peroxidase upon a peroxide. Arsenic as a more powerful peroxidase greatly increases the natural defence. Aluminium and iron are even more potent, and are non-toxic. After a time the ability of the host to produce active oxygen directly is lessened; hence it must be produced indirectly, by means of reduction, through the action of a perhydridase. The peroxidases are metallic, the perhydridases non-metallic; and in later stages of syphilis sulphur acts in a manner analogous to the action of aluminium, iron, and arsenic in early syphilis. Di-ortho-amino-thio-benzene is an efficient symptomatic remedy, particularly in later secondary syphilis and its complications and in recurrent and tertiary lesions. It appears also of value in cerebro-spinal syphilis. It has proved effective in some chronic processes non-syphilitic in character—e.g., lupus vulgaris and chronic leg ulcers.

RESULTS OF TREATMENT OF CHRONIC JOINT DISEASES BY CERTAIN PHYSICAL MEASURES.

BY JOHN J. GRACE, F.R.C.S. ENG.,

CHIEF ASSISTANT IN THE X RAY DEPARTMENT, ST. BARTHOLOMEW'S HOSPITAL.

WITHIN the last two years or so I have treated 24 cases of chronic joint disease by radiant heat and static electricity, with in a few cases electrothermic penetration (diathermy) also. Among these were 2 ankle-joints, 11 knees, 7 hips, 1 phalangeal joints of hand, 1 elbow, and 2 shoulders. The ankles did fairly well, knees very well, hips uniformly badly, elbow- and finger-joints badly, and shoulders fairly well.

1. One ankle was a case of Pott's fracture two years earlier in a lady aged 65. There was outward displacement and pain on walking. Bony thickening about fibula and some thickening of soft parts around tendo Achillis. The patient said she was very much better, and insisted on having as many as 35 treatments, as she was sure the improvement was continuous. That was two years or more ago. She now writes that she "can walk quite long distances, but standing soon becomes very painful." She adds that it is really not much better.

2. The other ankle was rheumatoid arthritis of the joint in a case of myxœdema. The joint condition had lasted six years, and now at 37 patient was completely disabled. There was general puffy swelling of the joint, great pain, but no

grating on movement. She had about 50 treatments, at the end of which the joint still looked very bad, largely because of general anasarca of the limbs, as having returned to work she was on her feet a good deal. She said the pain and use of the limb were much better. She has kept her position as a cook for nine months since treatment ceased.

The larger number of knees treated enables a better judgment to be formed of results to be expected in these cases. Six cases I regard as either rheumatoid or osteo-arthritis, some certainly, others probably. To take the two worst first:—

1. A soldier had had some loose bodies and synovial fringes removed from both knee-joints, and the diagnosis of rheumatoid (*sic*) arthritis was then definitely made. When he came under my care the wasting of his thigh muscles was extreme and his mental condition one of despair. There was grating on movement and various knobby points could be felt around the joints. He attended almost daily for about three months and then rejoined his regiment after passing a medical board. Afterwards he wrote that he was playing tennis and polo three times a week, and he is now with his regiment in France.

2. The next case is equally instructive. The patient was 52 when I first saw her two years or more ago. Sixteen years ago injured left knee; had had pain under knee-cap off and on since. Two years ago right knee similarly affected. Left very bad last three months; right getting steadily worse. Grating in both joints for two or three years. Both knees showed lipping of patellar articular surfaces. In addition, the left knee showed enormous thickening of synovial membrane. The patient has had a great deal of treatment from time to time. As a result, the synovial thickening and pain are gone. She has walked as much as 15 miles without pain, and without examination no one would think there is anything the matter with her knees at all. The lipping remains. Quite a bad relapse last autumn yielded quickly to treatment.

3. This case is, I think, one of rheumatoid arthritis. Patient, aged 46, had stiffness for 18 months first in her left knee, then in right. Began acutely with some pain and rise of temperature; stiffness followed. Pain like neuralgia on sitting for a while, and then again on rising. Creaking of joints. She had ten treatments without result and gave it up. She was one of my first patients, and if she came to me now I should urge a longer trial, though most people who are going to reap benefit do so before ten treatments. I am indebted to Dr. T. J. Horder for permission to publish the notes of this case.

4. Patient, aged 66, complained of aching pain down legs at night and knees getting stiff; a little grating on movement. Evidence of rheumatoid arthritis in fingers and some stiffness in shoulders formerly. She had ten treatments in 1912. I saw her a few days ago. She says she has had no return whatever of trouble in her knees.

5. Patient, aged 40, was kept awake at night in February, 1914, by pain in her left knee. It improved and got bad again in April. Since then until July, 1914, when I saw her, had been getting about, sometimes with a crutch, sometimes without; limping badly; pain very slight now. There was swelling of joint, partly due to fluid, but chiefly to synovial thickening. Considerable wasting of thigh muscles; much grating. After ten treatments patient refused to continue as she said she was quite well. She was certainly much better, and three months later the knee appeared normal except for the grating. I am indebted to Dr. Hugh Roger-Smith for permission to publish the notes of this case.

6. Corporal ——, R.F.A., sent to hospital as a case of chronic synovitis. Extra strain of mobilisation, he says, caused the knee to swell. Very bad at first, better now, but weak and painful on walking. Had been under treatment for two months by rest in bed with limb in a splint, and then by pressure. There was fluid in the joint and synovial thickening. This patient immediately improved and was encouraged to use his knee instead of sparing it, but he always relapsed just as I hoped he was well. After 20 treatments, I sent him to the dental department where five molars were extracted. After that he rapidly got quite well, but I have no confidence in the permanence of his recovery, as all his molars are bad and should be extracted.

7. Miss —— had given her knee a kind of twist in May, 1913, and again in June, 1913. It swelled up and became painful on walking; rest in bed relieved it. In September it got bad again. There was slight swelling due to fluid in the joint and slight tenderness to pressure at inner aspect of head of tibia with perhaps a little bone thickening there. It got well in six treatments and has remained well to date.

Three of the above 7 cases had pyorrhœa when they came under treatment; two others had had it. Two had no pyorrhœa and no history of it. The other knee cases are a little difficult to classify:—

One gave a history of injury at polo. The knee swelled up from time to time and was then painful. Then the other knee appeared to get weak at tennis. A few treatments to both knees, perhaps 12 in all, seemed to put them quite right.

Another patient had frequent attacks of acute synovitis in the right knee. Ordinarily there is a good deal of creaking in both joints. When seen he had much fluid in the right joint. It got well in three days.

Yet another had twisted his knee two years before I saw him. It was now, as he described it, unreliable, weak at cricket and annoying in that way. It never gave way suddenly. He was quite unimproved by my treatment, but six months after, when on a hunting expedition, he wrenched his knee badly. It swelled up, got very hot and inflamed, and has given no trouble since. A bonesetter could have made much capital out of this knee.

I welcome a bad knee, but do not feel enthusiastic when a patient tells me he has rheumatism in the thigh or hip, which too often means, in my experience, advanced osteo-arthritis of the hip-joint. Sometimes, too, cases of osteo-arthritis say they are suffering from sciatica. I have treated seven cases; no successes. Four of them were shown by skiagrams to be advanced cases of osteoarthritis with numerous osteophytes around the joint. The other three were not X rayed, but two had stiff hip-joints and the third much muscular wasting and an outwardly rotated thigh. Of the seven, four said they derived some benefit, but it was not obvious to me. It is possible, however, that the treatment strengthens the muscles to some extent.

Note.—Since writing the above I have treated two further cases. A skiagram in one showed marked changes in the joint, and, as I expected, there was no improvement. The other showed no joint changes in the skiagram, but there were marked stiffening and restricted movement in both hip-joints, particularly the right. This joint was treated by diathermy followed by the static wave-current, and after a month of daily treatment there was notable improvement in the lameness and in the movements at the joint.

Of osteoarthritis in the fingers I have treated one case only. There was no improvement. Of elbow cases one was treated. I cannot be sure what this was. It was characterised by great tenderness over the olecranon. I could not detect any of the usual evidences of osteoarthritis. It did not improve. Two shoulder cases were treated.

1. Male, age 51. Has had glycosuria 15 years. Evidence of osteoarthritis not very marked, a little grating, some wasting of deltoid, and pain in the shoulder on movement. Some limitation of movement. After six weeks' treatment he was very much better, had less pain and more use in the arm.

2. Male, age 40. Has had pain in right shoulder-joint for 25 years. He could play tennis in summer of 1913; now arm is completely useless. X rays showed partial ankylosis. There was great wasting of all shoulder muscles. After 21 treatments patient was very much improved in every way; could use his arm more and had much less pain. In addition to treatment from me, he had treatment by injections of rheumatic phylacogens to which he reacted very severely once. It is now about five months since treatment ceased. He writes that there is little or no pain in the shoulder, in which, however, I should imagine that ankylosis is complete. The use of the arm is much improved. I am indebted to Dr. Byres Moir for permission to use the notes of this case.

In comparing these results the contrast between knee- and hip-joints is striking. The other joints have been too few to form any judgment. The first cause to consider is the great difference in the joints in (1) character of articulation; (2) blood-supply; and (3) depth from surface.

Character of articulation.—Owing to the form of the hip-joint articulation and the mutual adaptation of the bones entering into the joint structure, an inflammation not giving rise to much pain will not early impress the patient as of great importance. Increasing stiffness will be put down to muscular rheumatism, and not until the disease is far advanced either in the way of calcification or of distortion will he realise that something serious is the matter. On the other hand, the integrity of the knee-joint depends much more on its ligaments. As soon these are inflamed they yield a little, and a sense of weakness is observed. Further, owing to the superficial character of the joint, fluid in it can quickly be detected and points tender to pressure found by the patient. Again, osteophytic deposits having occurred, they, or loose synovial fringes, may become impacted between joint surfaces, leading to locking of the joint, attacks of inflammation, &c. Thus, knee-joint cases come earlier under observation than those of the hip.

Blood-supply.—Just as its superficial position and its character bring the knee-joint earlier under treatment, so that position with its rich supply of blood-vessels aids in recovery. Looking upon the treatment as a combination of active hyperæmia with deep massage, we can see why this acts in the one joint and fails in the other. The light applied to the knee causes its blood-vessels to dilate and bathe all the tissues in a flow of lymph. Then the electric current is applied. The whole body is alternately charged and discharged from the knee, and at each discharge every muscle fibre in the neighbourhood contracts, acting as a pump to help the blood and lymph upon its way.

Depth from surface.—The knee-joint is thus easily reached by the forces brought to bear upon it, but the hip-joint is deep-seated and has relatively a poor blood-supply. It is improbable that the light penetrates far enough to dilate the deep vessels. Again, it is difficult to apply the electric current in sufficient strength to penetrate deeply enough, as these cases are often very tender to the wave current. Cases not tender are those in which destruction of bone predominates and which are certainly past all remedy. My hip-joint cases laboured under another disadvantage—that of age. The average age was 65 years, against 49 years in the knee cases.

The other cases are hardly numerous enough to call for comment. Theoretically, ankles, elbows, and shoulders should all do better than hips. In future I should be inclined to treat hip-joints by diathermy followed by the static wave current. As the highest temperature produced by diathermy is midway between the two electrodes, we would get it just where it is wanted—in the joint, and the subsequent static deep massage could be given with greater hope of benefit.

In conclusion, I should point out that these results are obtained with a high candle-power lamp giving at least 500 c p. from a single filament. I now use 3000 c.p. and think it is better than the lower c.p. lamp. The static machine used should be capable of giving at least an 18-inch spark between prime conductors with one side grounded. With suitable electrodes and a sufficient interval between contraction, very powerful and penetrating currents are tolerated. In treating the knee, for instance, an 18-inch spark gap is borne with ease.

Welbeck-street, W.

NOTE ON A CASE OF HEART-BLOCK SHOWING LARGE AURICULAR WAVES IN THE FEMORAL TRACING.

BY A. W. FALCONER, M.D. ABERD., M.R.C.P. LOND.,
ASSISTANT PHYSICIAN, ABERDEEN ROYAL INFIRMARY.

THE following case was admitted into the Aberdeen Royal Infirmary on June 17th, 1915, under the care of Professor A. W. Mackintosh, to whom I am indebted for permission to publish it.

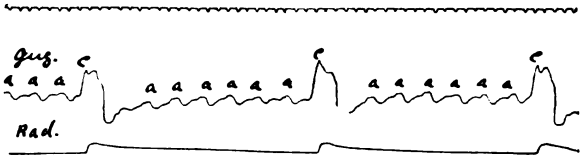
The patient, a male aged 60, had for some two months suffered from shortness of breath on exertion, but he had continued at work until June 15th. On that date he had an attack of giddiness and vomiting. On attempting to get out of bed next day he lost consciousness, and came to himself on the floor with a cut on his head.

On admission to hospital the patient lay in bed in any position, without discomfort. His only complaint was the frequent occurrence of "queer turns," during which he frequently lost consciousness. While under observation he had numerous typical epileptiform attacks, associated with marked slowing of the pulse. The apex beat of the heart was in the fifth interspace just inside the nipple line. There was a slight mitral systolic murmur. The ventricular beats were at times as slow as 12 a minute, and between the ventricular beats regular auricular beats could be very distinctly heard. These contractions could be heard both at the base and the apex, but were most distinctly heard over the apex. For some time after admission the pulse-rate varied from 12 to 18 beats a minute. A fortnight after admission it rose to 60, but in a week it again fell to between 32 and 40. During the first fortnight the patient had numerous long ventricular pauses, many of which were accompanied by epileptiform or giddy attacks. During this period the breathing was very markedly of the Cheyne-Stokes type, but later with the diminution of the heart-block the Cheyne-Stokes respiration disappeared. For some days after admission the ventricular rate varied from 12 to 18 a minute, the auricular rate remaining constant at 78. The ventricular rate was never absolutely regular for more than a few beats, and there were frequent long ventricular pauses.

In Fig. 1 the upper tracing is from the jugular vein, the lower from the radial artery. The time-marker is one-fifth of a second. During the long pause in the radial tracing the auricular beats continued unaltered.

FIG. 1.

FIG. 2.



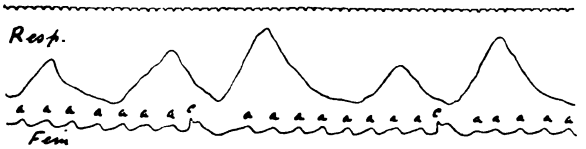


FIG. 3.

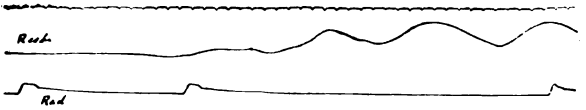
In Fig. 2 the upper jugular tracing shows a regular auricular rate of 78; the lower radial tracing a slow, irregular ventricular rhythm. It will be noted that there is no evidence of auricular waves in the radial tracing.

Fig. 3 is a continuation of the same tracing, in which the upper tracing represents the respiration, and the lower tracing is taken from the femoral artery immediately below Poupart's ligament by means of a Mackenzie tambour. It will be seen that there is the same slow ventricular rhythm as in Fig. 2, but there are in addition a series of large waves of exactly the same rate as the auricular waves in the jugular tracing in Fig. 2. There can be no doubt that these waves are of auricular origin, but as there is no evidence of similar waves in the radial tracing they cannot be true arterial waves. The femoral vein lies alongside the femoral artery, and, as Keith[1] has shown, the right auricle, vena cava, iliac and femoral veins form a cistern shut off from the venous system of the lower extremities by strong valves situated in the common femoral veins from 10 to 25 mm. below Poupart's ligament. I am of opinion, therefore, that these waves are not true arterial waves, but venous waves transmitted from the femoral vein.

The only other point of particular interest in the case was the occurrence of the long ventricular pauses. These only occurred during the time the patient was exhibiting marked Cheyne-Stokes breathing and disappeared when the Cheyne-Stokes breathing ceased. The long ventricular pauses always occurred exactly at the commencement of respiration following the period of apnœa. Fig. 4 is a simultaneous tracing of the respiration and the radial pulse showing this relationship.

FIG. 4.



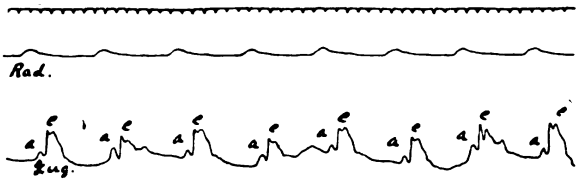


FIG. 5.

Three weeks after admission to hospital the condition of heart block passed off. Fig. 5, obtained on July 7th, shows a normal rhythm with a normal *a-c* interval. Later a 2-1 heart block again appeared and the patient was discharged from hospital on August 4th with this rhythm still present.

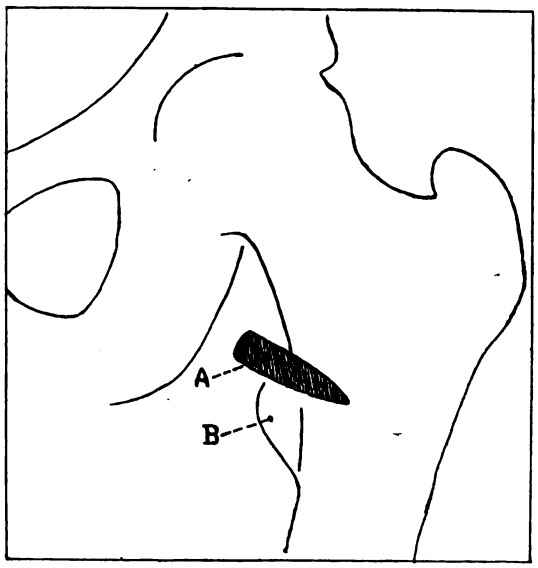
Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.



LATENT GAS BACILLUS INFECTION IN A HEALED BULLET WOUND.

BY D. PEARCE PENHALLOW, M.D.,
CHIEF SURGEON, AMERICAN WOMEN'S WAR HOSPITAL, PAIGNTON.

WHILE it is true that most of the gunshot wounds which are seen are infected to a greater or less extent, nevertheless not all of them give rise to clinical symptoms, and many heal in such a way as would lead one to believe that there was no infection. There has always been a certain amount of discussion as to the amount of infection carried in by bullets, and while we know that infected material, such as clothing, is carried in and may cause a badly infected wound, we also know that many wounds will heal very rapidly with no evidence of infection, and yet an infection may light up in such a wound if, even after a considerable lapse of time, any operative procedures are necessary in the scar track formed by the projectile.

The following case is reported as illustrating this fact and also as showing a very severe gas bacillus infection following the removal of a bullet from a thigh several weeks after the soldier had been wounded and after the wound was entirely healed.

Private ——, aged 29, while making a charge at the Dardanelles on August 8th, 1915, was wounded through the left hip. He crawled into a shelter out of the line of fire and had to remain there for 10 hours before he could be brought back. He was then taken to the dressing station where the

Tracing from radiogram showing the bullet A lying in the region of lesser trochanter B.

wound was treated. The next day, while being transferred on a stretcher, he received another bullet in his right hip. He was put on a hospital ship and transferred to Alexandria, where one bullet was removed from just above the knee. He was admitted to the American Women's War Hospital, Paignton, on August 26th. Examination at that time as follows. Well-developed nourished man, came in as an ambulatory case. General physical examination: Negative, save as follows: 2 inches behind anterior superior spine on right side is a small healed wound. Just on outer side of right leg 1½ inches above right knee is a small incised wound, slightly infected, where bullet was removed. On left side just over tuberosity of ischium is a small healed wound. Palpation about ischium elicits considerable pain; patient unable to sit on left side, as left buttock is very tender, and he states that it feels as if something sharp were sticking into him. X ray taken shows bullet lying in region of lesser trochanter and posterior to it. The wound just above the knee healed uneventfully. There was considerable doubt as to whether it would be wiser to remove the bullet from the thigh or to allow it to remain. The patient, however, complained so much of pain on sitting down that it was thought advisable to make an attempt to remove it. The bullet was very carefully localised by means of the fluoroscope on several occasions and showed very little change of position, but remained just on the level of, and posterior to, the lesser trochanter.

Oct. 9th: Operation. With the patient lying on his face a 3-inch incision was made on the posterior aspect of the thigh just below the gluteal fold, the upper limit of the wound being at the fold. The incision was carried down through the deep fascia and the muscles were separated, but it was found impossible to reach the bullet without enlarging the incision upwards, which was done. The bullet could be felt embedded in muscle and lying against the lesser trochanter, but owing to its depth it was found to be very difficult to remove. A counter incision was therefore made in the buttock 2 inches above the upper limits of the first incision, and a finger inserted through this down to the bullet, which could then be manipulated by means of a finger above and a finger below, and by this method it was freed from the surrounding muscles and removed. No evidence of encapsulation and no pus found. The wounds were sutured in layers and closed without drainage. Good ether recovery.

Oct. 10th: Temperature elevated to 102° F., pulse 116. Wound examined, not reddened, but thigh somewhat swollen and tender. Re-dressed. 11th: Temperature in afternoon became elevated to 104° and pulse 120. Wound again examined, and whole thigh found swollen, tense, reddened, and indurated; some crepitation in skin. From the wound itself a brownish serum was exuding, and when the sutures were removed some bubbles of gas escaped. There was also the characteristic odour of gas bacillus infection. The patient was immediately taken again to the operating-room, etherised, and multiple incisions were made on the thigh. Infection was found to be deep down throughout the muscles and fascia. The wound was dressed with hypochlorous acid solution. Culture taken. Bacteriological examination showed abundant B. aerogenes capsulatus. 15th: Condition improved. Temperature became less elevated. Wounds slowly healing up. 20th: Temperature and pulse practically normal. Condition of wounds satisfactory. The wound on buttock made for insertion of finger healed by first intention. 25th: Temperature and pulse normal. Wounds clean and granulating. 30th: Wounds closing and granulating in rapidly. Temperature and pulse normal.

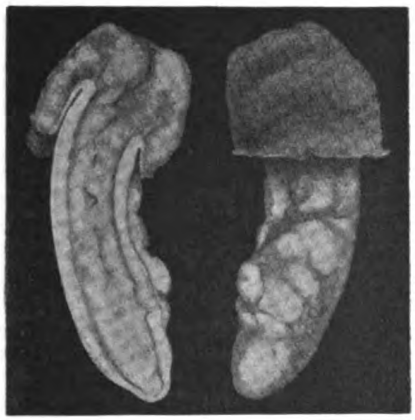
Nov. 12th: Since last note the patient had an uneventful convalescence, except for a slight elevation of temperature following operation for the closing of the wound in the upper part of the thigh in order to prevent a large painful scar. A few stitches at this time were removed and the wound drained, packed with iodoform gauze, and treated with hypochlorous acid. Culture at this time showed staphylococcus, but wound healed very rapidly in spite of it.

Jan. 12th: Wounds entirely healed. The patient up and around ward, and is now ready to be invalided.

It is interesting to note that the wound of entrance in the buttock was entirely healed at the time of admittance to this hospital, and it was not until the tissues had been traumatised by operative interference that any signs of infection manifested themselves. Also, that at the time of operation no evidence of infection, such as encapsulation of bullet or pus, was found.

Paignton.

A CASE OF INTUSSUSCEPTION OF THE VERMIFORM APPENDIX.



BY W. ALAN CURRY, M.D. MCGILL, F.R.C.S. ENG.,
ACTING SURGEON, GREAT NORTHERN CENTRAL HOSPITAL;
AND
ERNEST H. SHAW, M.R.C.P. LOND.,
DIRECTOR OF CLINICAL PATHOLOGY, GREAT NORTHERN CENTRAL HOSPITAL.

A REASONABLE conclusion to reach after a study of the following case is that the patient probably had several attacks of catarrhal appendicitis, and the last attack resulted in an intussusception into the cæcum.

A girl, aged 8, was admitted to the Great Northern Central Hospital, London, at 6 P.M. on Dec. 19th, 1915. She complained of pain in the stomach for three days. There was nothing of interest in her past history, except that during the previous year she had at least three attacks of epigastric pain accompanied by vomiting, which confined her to bed for a day or two. The present illness dated from Dec. 17th, when she came home from school and complained of abdominal pain and vomited several times.

The bowels were opened the following day after a laxative; no blood or mucus was noticed. Pain was intermittent during the 17th or 18th, and during the exacerbations she would scream out. On admission her temperature was 99·6° F. and her pulse-rate 128. On examination a swelling could be seen beneath the upper portion of the right rectus muscle. On palpation a well-defined mass could be felt in the region of the ascending colon just below the costal margin. There were muscular rigidity and tenderness over it. The chief site of tenderness was over McBurney's point. The abdominal reflexes were present. Rectal examination was negative. The most obvious diagnosis rested between appendicitis with abscess or intussusception.

An operation was promptly performed. A four-inch incision was made through the outer edge of the right rectus sheath and the peritoneal cavity opened. The small intestines were packed off to the inner side by large gauze mattresses. On introducing the hand the mass was distinctly felt in the right hypochondriac region. On delivery

Intussusception of the vermiform appendix.

it proved to be an intussusception of the appendix into the cæcum, which had increased in size at the expense of the cæcum. The cæcum had a well-developed mesentery and was very mobile. The intussusception was readily reduced by compressing the apex until the proximal ¾ inch of the appendix was reached. The appendix could not be further reduced because of the firm adhesions uniting the peritoneal surfaces. The adhesions were separated by means of a probe without any effect. The outer portion of the cæcal wall was œdematous, and its peritoneal covering presented a split about 1 inch in length. The cæcum was shut off by means of an intestinal clamp and the appendix excised, together with about one inch of surrounding cæcal wall. This was closed by a continuous through-and-through stitch of catgut and then buried by interrupted Lembert stitches. The split in the peritoneal coat was also covered in by a few Lembert stitches. A rubber drainage-tube was placed to the outer side of the cæcum and brought out through the lower margin of the wound. The after-history was uneventful. The drainage-tube was removed in 48 hours, and the patient made an uneventful recovery.

Description of specimen.—The specimen consists of the vermiform appendix and a portion of the wall of the cæcum. The appendix is 1¾ inch in length, and its proximal end is invaginated for about 1/3 inch into the cæcal wall. The peritoneal blood-vessels of the appendix are congested and the tube is thickened and firm. The cæcal mucous membrane is much swollen and congested. A longitudinal section through the specimen reveals a thick muscular wall and the lumen filled with swollen mucous membrane of the appendix. The mucous membrane of the cæcum surrounds the base of the appendix in the form of a large nodular mass. In this mass can be seen the reflected peritoneal coat at the appendix. The lumen of the organ can be traced in the midst of the thick mucous membrane.

Microscopic examination.—All the coats of the appendix are greatly thickened, especially the mucous layer. The epithelium is intact. Groups of small round inflammatory cells are present in the peritoneal covering. At the base of the appendix the tissues are œdematous. The cæcal mucous membrane is necrotic in places. The above changes are similar to those seen in many appendices which have been subject to attacks of "catarrhal" inflammation.

We are indebted to Mr. G. B. Mower White, senior surgeon to the Great Northern Central Hospital, for permission to publish this case.

A CASE OF TETANUS-LIKE SPASM LOCALISED TO THE WOUNDED LIMB.

BY G. T. MULLALLY, M.B., B.S. LOND., F.R.C.S. ENG.,
CAPTAIN, R.A.M.C., SPECIAL RESERVE.

THE following case bears a close resemblance to other cases which have appeared recently in THE LANCET, to which I refer later:—

Private —— was wounded by a shell on the afternoon of Dec. 16th, 1915. After passing through a field ambulance, where he was dressed and given a prophylactic dose of 1500 units of antitetanic serum, he was admitted to the clearing station the same evening. He had evidently lost a large quantity of blood, as he was very blanched and had no radial pulses. He had a compound fracture of the lower end of the right femur, with much laceration of the soft parts and rupture of the femoral vessels. Higher up in the same thigh two fragments of casing, each about the size of a walnut, had entered from behind and lodged under the skin over the anterior aspect of the thigh. In addition the left eye was destroyed and there were some small wounds of the right arm. As his condition improved somewhat with warmth and four pints of axillary saline, I took him into the theatre at about 10 P.M. Since it was evidently impossible to save the right leg, I took it off rapidly by a simple circular amputation of all the tissues in the same plane. I was unable to get above all the damaged area by this means, and as it was I cut across the track of the upper of the two fragments embedded in the thigh, and then cut away as much damaged muscle as I could distinguish at that early stage. At the completion of the operation he was given five pints of saline intravenously. He was much better in the morning, but on the evening of the 17th he looked much worse again, vomited several times, and complained of pain in the stump. His pulse was 160. Examination showed gas gangrene of the whole inner side of the thigh along the track of the fragment already mentioned. He was given gas and the gangrenous area was laid widely open. He remained apparently *in extremis* all the next day, but on the 19th (fourth day) he was better, and as much as possible of the gangrenous area was cut away. He continued to make progress during the next few days, although the wound, of course, remained very foul and did not show much sign of healing. On the 24th (ninth day) he was again taken to the theatre and the remaining sloughs were cut away under an anæsthetic. On the following day the sister reported to me that sleep had been disturbed by twitchings in the stump, which had kept the patient awake but had not been painful. These painless spasms were evoked during the next three days whenever he was dressed, but always passed off in about an hour. There were no other signs of spasm to be detected. I attributed them to an ascending neuritis. On the 28th (thirteenth day), when he was being dressed, the spasms occurred with great intensity, and were accompanied this time by excruciating pain, which caused him to scream and sweat profusely. The pain was so great that I was obliged to give him chloroform almost at once. This attack lasted about an hour, and similar attacks occurred during the same morning. As I was still obsessed with the idea that I was dealing with an ascending neuritis I anæsthetised him again, cut away as much of the anterior crural and sciatic nerves as I could reach, and then injected both trunks, one at Poupart's ligament and the other at the sciatic notch, with absolute alcohol. Both nerves were very red and enormously thickened. He was in no way improved by these measures, and on the following days the attacks recurred again and again and had to be controlled by chloroform, as large doses of morphia and bromides and chloral were quite without effect. The patient rapidly became exhausted, and died on Dec. 31st. He never showed any sign of general spasms, but on the morning of his death his facial expression was distinctly suggestive of a risus sardonicus.

During the case tetanus was, of course, considered, but the symptoms were so atypical that I thought it was most unlikely, and I fell back on the very unsatisfactory label of ascending neuritis. It was not until I saw the articles by Lieutenant-Colonel R. D. Rudolf [1] and Captain T. B. Mouat [2] that I had any further light thrown on the subject. I have not, with the limited means at my disposal, been able to find any other references on the subject, save a brief note of a case described by Pozzi.[3] In view of these cases I feel sure

[1] Tetanus like Spasm Localised to the Wounded Limb, THE LANCET, Nov. 13th, 1915, p. 1084.
[2] A Case of General Tetanus following Localised Tetanic Spasms of the Injured Limb, THE LANCET, Jan. 22nd, 1916, p. 188.

now that the one I have detailed was tetanus, and that the proper course would have been to administer antitetanic serum intrathecally as soon as the first spasms were noticed.

It is interesting to note that in my case, in Captain Mouat's case, and in one of those described by Colonel Rudolf, the conditions followed immediately on operative interference, which opened up fresh tissues.

Medical Societies.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.—A meeting of this society was held on April 6th, Major A. H. Buck, R.A.M.C. (T.), the President, being in the chair.—Dr. Duncan Forbes read notes on a case of Meningitis following infection of the sphenoid bone, and showed post-mortem specimens illustrating the case. In this case a streptococcal infection had spread from the nasal cavity to the meninges through the sphenoid bone. Interesting points, apart from the very definite evidence of the route of infection, were an illness lasting 17 days with no rise of temperature until the twelfth day of illness; Kernig's sign following neck stiffness; and persistent severe headache throughout, and swelling over the temporal fossa.—Major C. F. Bailey showed a skiagram of Two Separate Calculi in the Left Ureter of a woman. Mr. D. W. Livingstone and Major T. H. Ionides, under whose joint care the patient had been, described the case, which was discussed by the President.—Dr. A. Winkelried Williams showed specimens illustrating a case of Rodent Ulcer in a young man. Both lower eyelids were affected and there were two growths on the side of the nose.—Captain W. Barrington Prowse read a paper entitled "Some Notes on the Use and Misuse of X Rays." He referred to their extremely wide field of usefulness in medicine and surgery, both for diagnosis and treatment, and the necessity for specialisation in this branch of medical work, and deplored the fact that the use of X rays by unqualified or even uneducated men was allowed, and even sometimes encouraged. There was a tendency to look upon radiography too much as simply photographic work to supply definite black and white evidence, and the necessity for the extremely careful handling of this evidence was often overlooked. There should be a much closer consultation between the radiologist and the medical man in charge of the case under examination. Some of the physical properties of X rays were discussed, and their bearing upon radiographic work in general, and upon special cases in particular, and it was pointed out how faulty technique would lead to error and wrong diagnosis. Mechanical and other difficulties in their application were also referred to, and the means by which they are overcome. With regard to particular uses in diagnosis, special attention was drawn to the necessity for an X ray examination in all cases of injury or possible injury to the bony skeleton, and the impossibility of trusting to a screen examination alone for a diagnosis of absence of fracture. The localisation of foreign bodies and the diagnosis of abnormal conditions in the various regions of the body were discussed, special mention being made of tubercle in connexion with the various forms of chronic disease in the bones and joints, and also as regards the diagnosis of its presence in the lung. The use of bismuth and X rays in the investigation of diseases of the digestive organs was also specially referred to, and the influence it has had upon our knowledge of the alimentary canal and what takes place in it. In dealing with examinations of the urinary tract for stone, &c., the necessity for a complete investigation of the whole tract was pointed out, and also the necessity for a very thorough preparation of the patient beforehand. Turning to treatment, some general remarks were made upon the influence of the rays upon living tissues, on the different effects of mild and heavy doses, their cumulative effects, and so-called selective action. The need for extreme care in the therapeutic use of X rays was insisted upon, and some general indications were given of the circumstances in which they were most likely to be useful. Various diseases in which they had been used with success were mentioned, and in speaking of parasitic diseases of the hair exception was taken to routine employment in cases of ringworm. Their value in malignant disease was briefly discussed, and the reasons for limitation of usefulness in this condition were referred to.—The paper was discussed by the President, who emphasised the supreme importance of the use of X rays in cases of fracture. He pointed out the difficulties caused by the movement of foreign bodies in the abdomen and in joints, and quoted a case of myositis ossificans. Foreign bodies in the pelvis were hard to locate owing to the difficulty of obtaining a satisfactory lateral view.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—A clinical meeting of this society was held on April 7th, Dr. Leonard C. T. Dobson, the President, being in the chair.—Among the cases shown were the following:—Mr. H. Tyrrell Gray: 1. Sarcoma of Tibia in a male, aged 10 years, treated by radium. 2. "Club Hand," congenital absence of radius; bone graft; result (with skiagram); female, aged 2¾ years. 3. Knee-joint Changes in a female child, aged 11 years, resembling osteo-arthritis of adults (? throat infection) (with skiagrams). 4. Central Tuberculosis of Radius in a female aged 4 years; excision of half radius; bone graft; result. 5. Carcinoma of Floor of Mouth in a male aged 72 years.—Dr. T. Grainger Stewart: Post-diphtheritic Paralysis in a male aged 10 years.—Dr. A. J. Scott Pinchin: Urticaria with Dermographia in a male aged 10 years.—Dr. J. M. Bernstein: Specific Osteitis of Tibia in a female.—Mr. J. G. Pardoe: Carcinoma of Penis.

New Inventions.

WIRE HELMET FOR CASES OF LOSS OF BONE.

THE helmet here illustrated is constructed of crossed steel wire and is similar to a fencing mask. It is made to a mould, covering the vertex and the underpart of the occiput. The wire-netting is soldered to a ribbon of tin and this is covered by suède. It is claimed for this helmet that it is very protective, easily worn, and causes no pressure at any one point. The hat can be measured to fit over it. It does not overheat the head. The picture shows the helmet adjusted. The shaded circle shows the extent of the loss of bone. The mask was made for me by Messrs. Allen and Hanburys, Ltd., Wigmore-street, London, W., for the case of a man who was wounded at Loos and in consequence has a loss of bone in the right temporal region of 3¾ by 3¾ inches.

GEORGE DAVIS, Captain, R.A.M.C.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—An ordinary meeting of the Council was held on April 13th, Sir Frederic Eve, Vice-President, being in the chair.—A vote of thanks was given to Lady Strathcona for presenting to the Museum two complete skeletons of musk oxen.—It was resolved, on the recommendation of the Library Committee, to continue until further notice the closing of the Library at 6.30 P.M. instead of 7 P.M.—It was resolved, on the recommendation of the Jacksonian Committee, that the Jacksonian Prize should not be awarded for 1915. The subject chosen for the year 1917 is "The Causation, Diagnosis, and Treatment of Traumatic Aneurysm, including Arterio-venous Aneurysm."—On the recommendation of the Triennial Prize Committee it was resolved that the Triennial Prize should not be awarded for the period 1913–15. The subject for the period 1916–18 is "The Development of the Hip-joint and the Knee-joint of Man."—It was resolved, in accordance with the recommendation of the Walker Prize Committee, to award the Walker Prize of £100 to Mr. William Sampson Handley. The Committee drew attention to the excellent investigations carried out by Mr. Handley on the centrifugal spread of mammary cancer by the lymphatics, on which he founded the doctrine of permeation. These investigations have influenced the surgical treatment of cancer of the breast during the last five years.—The Council proceeded to the election of two Members of 20 years' standing: Percy William Bassett-Smith, C.B., R.N., and James Frank Colyer.

THE LANCET.

LONDON: SATURDAY, APRIL 22, 1916.

The Treatment of Venereal Diseases by the State.

THE President of the Local Government Board, Mr. LONG, received last week a deputation from the National Council for Combating Venereal Disease, which came before him to urge that immediate effect should be given to the recommendations of the Royal Commission on Venereal Diseases, particularly to those dealing with the provision of adequate facilities for the diagnosis and treatment of the conditions as they manifest themselves among the mass of the people. The recommendations especially alluded to were those which expressed the view that institutional treatment should, as far as possible, be provided at general hospitals, and that local authorities should, as the first step in the preparation of their schemes, approach the general hospitals in their areas with a view to making arrangements for treatment. It was the view of the Commissioners that treatment at any institution included in a local authority's scheme should be free to all, and that there should be no refusal to treat a patient who is unwilling to go to his own doctor, or who desired to be treated in a particular area where he or she was not resident. It was further recommended, so as to remove practical difficulties as well as natural reluctancies, that special arrangements, such as evening clinics, should be made for the treatment of out-patients at hours convenient to the working classes, and that local authorities should be empowered to supply salvarsan or its substitutes gratuitously. With full knowledge that local authorities vary much in the interpretation of their responsibilities, the Commissioners suggested that in any case where a local authority refused to provide for treatment the Local Government Board should be empowered to make arrangements directly with hospital authorities. Finally, the Commissioners recommended that the expenditure on schemes of treatment should be assisted by grants from Imperial funds, suggesting that the grants should be equivalent to 75 per cent. of the expenditure incurred by local authorities. In this event the Local Government Board would be responsible for the distribution of the grants, and the Commissioners considered that it should be left to the discretion of the Board to lay down the conditions subject to which the grants would be paid. It was to urge upon Mr. LONG the dangers of delay in thus providing for the State treatment of venereal diseases that the deputation attended at the Local Government Board.

It may be remembered that one of the general conclusions of the Commissioners, in summarising their own recommendations, recorded a strong opinion that the conditions now existing, as well as those which must follow on the conclusion of the war, imperatively required immediate action. The percentage of infection in the naval and military forces may not be now greater than it is in normal times; but the total of infected persons has increased, and the opportunities of wide dissemination have increased also. The military authorities are doing their utmost to provide treatment; we have published many communications which show the anxious care and strenuous work which have been and are being expended in this direction. But the civil population requires similar consideration, for it is only too probable that after the war the infection may be widely spread, largely through ignorance, and that in districts previously free the medical profession may have serious incidences of venereal disease to cope with. The Commissioners, with an eye on this sinister probability, expressed conviction that it would not suffice to establish treatment centres in places where sailors and soldiers are congregated, and that these will be needed in most of the larger and in some of the smaller towns. "We realise," they said, "the claims of economy at the present moment, but ..... we believe that all necessary expenditure will be recouped by the results which can be obtained. ..... We wish to lay stress upon the needs of the future. The diminution of the best manhood of the nation, due to the losses of the war, must tell heavily upon the birth-rate, already declining, and upon the numbers of efficient workers. The reasons for combating, by every possible means, diseases which in normal times operate with disastrous effects alike upon the birth-rate and upon working efficiency are, therefore, far more urgent than ever before. Now and in the years to come the question of public health must be a matter of paramount national importance, and no short-sighted parsimony should be permitted to stand in the way of all means that science can suggest and organisation can supply for guarding the present and future generations upon which the restoration of national prosperity must depend."

It would be difficult to put the situation into briefer and more forcible phrases, or show more eloquently upon which side true economy must lie. We are not surprised that Mr. LONG was able to give the deputation introduced by Lord SYDENHAM a favourable answer; it is shown from his words that the advice of the Report of the Royal Commission on Venereal Diseases will shortly be taken in a practical way. When the Report appeared at the beginning of March there was considerable apprehension among those who knew the position, that its shrewd and provident recommendations might fail to be immediately translated into action on the score of the expense to be incurred. Some of the lay papers considered that the needful money, to say nothing of time and skill, could not be spent on the gratuitous treatment of venereal diseases at so critical an era in our history. We ventured to say at the time that this view was short-sighted. By hook or by crook the money should be found for the State treatment of

venereal diseases. The medical profession will play its part with ardour, and a combination of good intent, good science, and good money ought to go far to eradicate venereal diseases from among us, perhaps in a shorter time than a few years ago would have been deemed possible. When the local authorities are finding money they will want to know what it is required for; when they understand, they will give the money with both hands, and will educate their constituencies in order to justify the expenditure. Ignorance will thus be removed, and ignorance, colossal ignorance, is the chief factor in the spread of venereal diseases.

Amputations and Amputation Stumps.

THE Medical Department of the War Office has recently issued a memorandum on the subject of amputations and amputation stumps, a fact indicative of the importance of this surgical procedure. Amputation has been called the opprobrium of surgery, and though this epithet is quite undeserved, for by amputations lives are often saved, yet VELPEAU is in the right when he speaks of amputation as "the last resource of surgery." It is ever the surgeon's endeavour to save a limb if possible, and as an amputation often enables him to preserve life by this sacrifice, an amputation is more fitly termed "an humane operation." The wounds in this war may not produce a high percentage of amputations, but the horrific total of men engaged must lead to an enormous loss of limbs in the aggregate. The fathers of surgery approached the question of amputation from an identical point of view, though their reasoning and consequent procedure have so little in common with ours to-day. It was without doubt the fear of hæmorrhage that restrained the older surgeons from amputating, for we find that HIPPOCRATES speaks only of removing a limb after it has become gangrenous, and he directs that the incision should be made through the dead tissues, where there was no fear of loss of blood; but this operation, if an amputation it may be called, must have been of limited application and of little practical value. To CELSUS can be given the credit of advising that when a mortified limb has to be removed the incision should be made rather in the living tissue than in the dead; and though he says nothing in this connexion of restraining the hæmorrhage by means of ligatures, yet there can be no doubt that he used them in amputations, for he describes their use in hæmorrhage from wounds. The amputation which CELSUS employed was almost a clean cut through all the tissue, though he directed that the soft parts should be retracted as much as possible before the bone was sawn, and he endeavoured to draw the soft tissues together so as partly to cover the bone. We see here the design to produce a comfortable stump, though we do not hear of artificial limbs to be affixed to the stump until many centuries later. GALEN, a century after CELSUS, advised that the section should pass entirely through the dead tissues, and he agreed with HIPPOCRATES in removing the limb at a joint, giving as the reason that it was more speedy. There was clearly here no thought of a useful stump, and the ancient operator's eye was ever fixed upon the point of hæmorrhage. The patient might and probably did usually die, but it was hoped that he would not die actually under the knife and saw. From time to time attempts were made from earliest days to control hæmorrhage by means of tourniquets of one form or another, but they appear to have been inefficient, until in the latter half of the seventeenth century MOREL devised an instrument capable of restraining the loss of blood. The ligature well known to CELSUS was forgotten or at least neglected, and it was not until the time of AMBROISE PARÉ that the ligature regained its rightful place as the most efficient plan of stopping hæmorrhage. And then no widespread use of the re-discovered method took place, while more than a century later many surgeons continued to prefer the use of styptics or the actual cautery.

The principle being established that the incisions for an amputation must pass through healthy tissues, the reasons for amputation became the same however the injury was produced, and whether in civil or military circumstances. If the limb was expected to die it must be removed lest the patient should die, but there was prolonged difference of opinion as to the right moment for interference. Having regard to gunshot wounds alone—that is to say, coming to comparatively modern times—the best moment for amputation has been much discussed, and the most divergent views have been expressed. RICHARD WISEMAN, who has been called the Father of English Surgery, was strongly in favour of amputating as soon as possible, and on the whole that has been the opinion of most surgeons. The chief argument against immediate amputation is that the shock of the amputation will be added to the shock of the injury, and this double shock may prove too much for the patient's strength and he may succumb. About 100 years ago the surgeon-in-chief of the Prussian army issued an order that no amputation whatever should be done for gunshot injuries, with the result that one-half of the men with fractured limbs from this cause died, and many of those who survived were greatly deformed. With this heavy mortality we may compare the results obtained at the same time by LARREY, who had a mortality of only 25 per cent. after primary amputation in gunshot wounds. Before the advent of the antiseptic practice of LISTER it had come to be recognised that in nearly all cases the primary amputation offered a far better chance of recovery than the secondary, the only exception being amputation of the upper part of the thigh. When antiseptic methods began to be employed the death-rate at once fell, and the use of anæsthetics went far to limit the amount of the shock of the operation. Recent researches of CRILE have shown that the degree of shock can be reduced still more by the use of a local anæsthetic concurrently with the general anæsthesia. For various reasons, therefore, the

dangers of amputation have much declined in civil practice, and where in military practice the same advantageous conditions can be obtained the same good results may be expected. But the difficulty of avoiding sepsis and the frequency of multiple wounds and of comminuted fractures form very unfavourable conditions, while many of the cases where shock is present cannot await operation until the ideal anæsthetic technique can be employed—the delay would mean death.

In addition to consideration of the time of the amputation, of how to avoid shock, and of how to control hæmorrhage, the surgeon has to decide on the form of amputation to perform; and in this direction our surgery has much improved with the flexibility introduced by modern operators, who no longer confine themselves to classic routines, but attempt to make their procedures fit individual cases. Yet ancient learning and experience make themselves heard. The simplest and the oldest method of amputation is the circular, in which the skin, the muscles, and the bone are all divided at the same level; this method, which is sometimes associated with the name of ANTYLLUS, differs but little from that described by CELSUS, who, however, endeavoured by traction of the soft parts to saw the bone at a rather higher level. This method has recently been employed at the front with no small measure of success, for in very septic cases it gives the most thorough drainage possible, but it has the disadvantage that some subsequent operation is always required. In spite of this fact, the thoroughness of the drainage and the rapidity with which it can be performed render it an operation of the greatest value in the abnormal surgical conditions obtaining at the front. The circular amputation remained for centuries the regular method of amputation, but in course of time it became modified, the circular division of the skin being followed by a circular division of the muscles at a higher level, the bone being sawn at a higher level still. The names of CHESELDEN and PETIT are associated with this important modification. The results of this operation are, on the whole, very fair over a great range of cases, for though it is exceptional for the bone to be covered in, a very useful stump frequently results. But in all circumstances where no risk is entailed flaps are to-day designed as being the obvious way to secure a stump on which to fix an artificial limb. LOWDHAM, of Exeter, must be credited with the introduction of flaps about the middle of the seventeenth century, and though their formation by dissection was slow and painful before the days of anæsthetics, the introduction of the transfixion method confirmed the flap operation as the procedure of choice. With the use of anæsthetics the light skin flap formed by dissection became possible, and by the adjustment of the relative lengths of the flaps the surgeon found that he could ensure that the scar did not become adherent to the end of the bone.

The question of the best form of amputation, when the immediate risks have been considered, must be decided by the fact that the stump formed by the amputation will in time be required to support an artificial limb. All incisions and all flap arrangements must be made so that the resulting stump may lend itself to a prosthesis. The main purpose of the memorandum of the War Office, to which we have already referred, is to direct the attention of the officers of the Royal Army Medical Corps to the need for great attention being paid to the future usefulness of the stump. Though in most cases the actual site of amputation is determined mainly by the nature and situation of the lesion yet if due attention be paid to the subsequent functional utility of the stump, a slight modification of the amputation may render the stump particularly fitted for the application of an artificial limb. The memorandum has been admirably drawn up, and it should prove of very real value to the surgeon at the front and also at base hospitals, for it will serve to indicate those amputations which form stumps lending themselves conveniently to the fitting of an artificial leg or arm. The first duty of the surgeon about to amputate is to save the life of the patient, but when the risk to life does not overshadow the other desiderata of the operation, due attention should be paid to the needs of the artificial limb. Much of the after-comfort and usefulness of the soldier will depend on the judicious choice of the form of amputation employed.

Annotations.

"Ne quid nimis."

CERTIFYING SURGEONS AND THE COMMITTEE ON RETRENCHMENT.

THE recent report of the Committee on Retrenchment recommended that a saving of £12,500 per annum should be effected by dispensing with the reports of certifying surgeons on accidents. "We understand," the Committee said, "that the reports are now of little value and entail, in all serious cases, a duplication of the reports made by the inspectors. The Committee on Accidents in Factories recommended that legislation should be obtained to enable them to be dispensed with, and we concur in this proposal." A temperately worded memorandum issued by the Incorporated Association of Certifying Factory Surgeons dissents from the advice thus given by the Committee, pointing out that it was requested to suggest economies which might be effected "without detriment to the interests of the State," and examining the proposal from this point of view. This, no doubt, is the position which we all should adopt who criticise any effort made by the Government to diminish expenditure, whether the money which it is proposed to save would under normal conditions pass into our own pockets or into the pockets of others. At a time like this the interests of the State must be paramount, and personal interests must give way to public advantage. The personal interests of the certifying surgeons in this case are estimated for us by the Committee. It is proposed to save £12,500 per annum, an item but a small one in a vast national expenditure, and one against which must be weighed the value of the services dispensed with. This cannot be stated in a pecuniary

form. The certifying surgeon as distinguished from the factory inspector, who may quote the report of the certifying surgeon but cannot duplicate it, is the expert whose knowledge of injuries and of industrial disease and poisoning enables him to determine the causation of the physical conditions submitted to him; it is he only who, as an impartial authority, can decide that alleged physical conditions exist and that they are or are not caused by the accident to which they are attributed. In doing this he is brought into contact with the injured workman, whose story imputing his injuries to the accident he is able to corroborate or to reject. Of special importance is the work done by him in the investigation of cases of industrial poisoning. The Committee on Accidents did not, the memorandum of the Association of Certifying Surgeons points out, say more than that "much" of the certifying surgeons' work might be dispensed with. It did not find that all was superfluous or could safely be done away with. If the present recommendation means that the whole of the sum of £12,500 is to be saved, it implies that useful and superfluous functions are alike to be sacrificed, and we believe that in the case of the former the retrenchment would involve "detriment to the interests of the State."

SCIATICA AND MALINGERING.

THE practical necessity often occurs of diagnosing whether sciatica is genuine in cases suspected of malingering, and Professor G. Boschi describes in *Il Policlinico* (Practical Section, March 26th) a method of arriving at a correct solution. Subjective criteria are not sufficient, and an observant malingerer soon learns that pressure on certain points and movement in certain positions are expected to evoke pain and accommodates his behaviour accordingly; hence other criteria, objective and not capable of simulation, are necessary from a medico-legal point of view. Some of these symptoms are not invariably present; others depend on the gravity of the disease, on its nature or duration, such as, for instance, increase of tendon reflexes, local hypothermia, wasting, scoliosis, and increase in the amount of albumin in the cerebro-spinal fluid as demonstrated recently by Sicard. Professor Boschi, however, calls particular attention to organic expressions of pain apart from the operation of the will, such as pupillary, sphygmographic, and sphygmomanometric reactions. To elicit these Laségue's movement is performed on the affected limb, the angle formed with the plane of the bed when pain is produced being approximately noted; the movement is then repeated on the healthy limb, during which the pulse is counted and the armlet of a Riva-Rocci sphygmomanometer adjusted until the radial pulse is obliterated, and the condition of the pupils is observed. Laségue's movement is now repeated on the affected limb and the patient watched so that he cannot produce pain by other means such as tongue biting. If pain be caused there will be a sharp, transitory, but marked dilatation of the pupil to the extent of 3 to 5 mm. The part that nervous apprehension might play in causing pupillary dilatation would, if differing from that produced by examination of the healthy limb, not exclude painfulness, and as such would corroborate a positive indication. An assistant feels the radial pulse in connexion with the sphygmomanometer; increased arterial pressure caused by the pain will re-establish the pulse, but care must be taken that meanwhile the patient does not try to strain with a closed glottis, which will, as shown by Valsalva, increase artificially the arterial pressure. The assistant then counts the pulse; normally an increase of 8–10 beats a minute is caused by pain. But it is known that neurotic subjects may react to painful stimuli, with a still more marked increase, or, on the other hand, sometimes with slowness or irregularity of pulse, so that variations of this character must be considered also as organic affirmation of painful movements. The control of the reaction on the healthy limb disposes of some of the objections that are sometimes raised against these variations in the pulse—i.e., the indefiniteness and variability of the so-called "normal" with which the result obtained has to be compared, and the fact that numerical increases in the pulse may be due to psychical conditions of anxiety relative to the examination. At any rate, however, and this also applies to the other tests, it is highly improbable that painful stimulation of the affected limb will not cause differences in the reactions described in comparison with similar stimulation of the healthy limb.

RECENT WORK ON HAY FEVER.

Hay fever is chiefly regarded in this country as a very real, rather distressing, but not very serious complaint. It is otherwise in certain parts of America, notably about Baltimore, where it assumes such a severe character that many sufferers have to move into other districts when the spring or autumn fever becomes prevalent, and business may be seriously interfered with solely on this account. It is to that country, therefore, that we find ourselves indebted for some quite important researches on hay fever. There are two flowering groups which appear especially to induce the coryza typical of hay fever—the Graminaceæ, flowering in the spring, and the Compositæ, in the autumn. To one or other, more rarely both, certain people appear to be unduly sensitive, and an ophthalmic and a cutaneous test can be applied which will show whether a person is sensitive or not to one or the other. The character and manner of inducing the reactions are similar to those of tuberculin, but the substance used is a dilute pollen abstract. Dr. G. H. A. Clowes reports in the *Johns Hopkins Hospital Bulletin* for March, 1916, some favourable results which he has gained in the treatment of hay fever by the intravenous injection of dilute extract of the particular pollen to which the individual, by preliminary tests, has been found unduly sensitive. It is best to begin the treatment two or three weeks before the hay fever season commences. 1 c.c. of a solution of 1 in 5000 is injected, and this is repeated every three or four days until 12 injections have been given and the strength of the pollen extract solution has been gradually raised to 1 in 1000. In a series of 100 cases the results were as follows: In 25 to 30 per cent. marked alleviation; in 30 to 40 per cent. marked improvement; no effect in the rest. As regards the latter, however, these individuals were found not to react, or were found to be negative to any particular pollen test, so that it is probable that the special sensitising pollen had not been found for them. The above results were compared with a series of non-treated cases, all of which were badly affected. It is found that sensitiveness to the pollen redevelops at the end of three or four months after a course of injections. It is suggested, however,

that with continuous treatment over three or four years a cure may be effected, as it is noticed that in these cases there is a notable lessening of the attacks. Less effective than the pollen extracts is calcium lactate given in large doses, which also lessens to some extent the sensitiveness to hay fever. It is remarked that this effect is more readily produced in well-nourished individuals. One point hitherto not explained in relation to hay fever is that people may be affected even when living in a big city. But it has been discovered that even in these places the pollen can be found in the air in appreciable quantity.

EXPERIMENTAL DIETS CONTAINING IMPURE MILK-SUGAR.

ACCORDING to an interesting research carried out by Mr. J. C. Drummond in the biochemical laboratory of the Cancer Hospital Research Institute, London, it would appear that milk-sugar under certain circumstances may contain effective amounts of a growth-promoting factor. The results are published in the March number of the *Biochemical Journal*, just issued, and they are in entire agreement with those published in a paper by Mr. E. U. McCollum and Mr. M. Davis in the same journal in 1915. The suspicion was entertained that in many cases the experimental diets, presumably free from indispensable accessory substances, afforded a satisfactory diet because impure milk-sugar had been used and the impurity was an accessory substance. As Mr. Drummond now points out, our knowledge of the action of these unknown factors is so slight that we shall be forced to reconsider many of the conclusions which have been drawn from the results of feeding experiments, involving the use of diets which appear now not to have been pure. By "pure," of course, is meant that the carbohydrates, proteins, and fats present in the diet are free from those indispensable accessory substances to which the name vitamines has been given. It is desirable, therefore, that the experiments where impure milk-sugar was included in the diet should be repeated with milk-sugar about the purity of which there can be no doubt. It is significant that samples of milk-sugar obtained from reliable English firms as "pure" show the presence of a nitrogenous body, the average amount of nitrogen found being 0·024 per cent. There can be no doubt that on the one hand the failures to obtain body-growth with artificial food rations proves that purified elements in the diet were being dealt with, while on the other, when growth was established in similarly prepared diets, the impurities were not completely removed, and these impurities contained the growth-promoting accessory substance. The use of impure milk-sugar is a case in point.

THE FAILURE OF FUMIGATION AS A DISINFECTANT.

IN the *Boston Medical and Surgical Journal* of March 9th, Dr. W. W. Walcott, State District Health Officer of Massachusetts, describes some experiments which he made five years ago in conjunction with Dr. Curtis, chairman of the Newton Board of Health, from which he concludes that fumigation for the purpose of disinfection is useless. On looking up the literature of the subject he found that most of the experiments had been done under laboratory conditions. Dr. Walcott and Dr. Curtis arranged to carry them out as nearly as possible under service conditions. They secured two rooms exactly alike in the Newton Hospital. One was sealed and fumigated and the other used as a control. Inoculations were made upon compresses of cotton, linen, gauze, and sometimes on the wall. They were put on the floor, table, chairs, mantelpiece, window-sill, bed, and at various other places and elevations. Similar inoculations were made in the control room. Laboratory cultures were not used, because of the possibility of their being attenuated, but smears and swabs were taken from noses, throats, and ears in the contagious wards and from suppurating wounds. Thus live, virulent organisms were obtained. Every ordinary method of fumigation was used—sulphur candles, sulphur powder, formaldehyde candles, the apparatus for generating formaldehyde gas from 40 per cent. formaldehyde solution, potassium permanganate and formaldehyde in the proportion of 1 to 2, and a mixture of aluminium sulphate, formaldehyde, quicklime, and water. Fumigation was carried out for periods varying from 24 to 72 hours. All the proprietary preparations were tried under the same conditions. Every morning cultures taken from the fumigated room were examined first. When they were found dead it looked as if fumigation had done some good, but when the control cultures were examined they were also found dead—apparently they had died a natural death. On the other hand, in the case of a proprietary preparation of which one candle was guaranteed to kill every germ in a room, a little shrine was made of these candles and the inoculation placed in the centre. The germs lived through the experiment. The experiments were carried out for nearly a year, and the conclusion was reached that fumigation has no consistent effect upon cultures. The city of Newton therefore made fumigation optional, and ceased to perform it as a matter of routine. Other cities, such as Boston and New York, then discontinued it. Dr. Walcott says that all that is necessary is that the sick room be scrubbed, scoured, painted, and papered, but if this is not possible a good safe rule is to scrub with yellow soap and hot water as high as a man can reach.

MIDDLE-EAR DISEASE DUE TO VINCENT'S ORGANISM.

Vincent's angina is recognised as a fairly common throat affection; microscopical examination of the exudate reveals the small spirillum characteristic of this condition. There is also a certain tendency for the naso-pharynx to be involved. It has only recently been noted, however, that Vincent's spirillum may be responsible for certain cases of middle-ear disease. Dr. J. A. Mulholland has reported in the *Annals of Otology, Rhinology, and Laryngology* 16 cases of this disease. In 13 the seat of the infection was in the middle ear and auditory meatus; in 3 more cases this was associated with mastoiditis with much necrosis, and two of these cases succumbed. The onset of the disease is insidious and not associated with any pyrexia or any marked degree of pain; there is only a free discharge of pus from the external auditory meatus. It is significant that in very many of the cases there was a history of "running ears" for months or even years; in some, considerable disease of the teeth was present. Examination shows much greenish pus, and on the walls of the auditory canal is seen a greyish membrane, which on removal leaves a bleeding surface. Perforation of the drum is frequent. There may be

swelling and œdema of the auricle. Where the mastoid is involved the cavity is filled with a spongy, putrid mass with obliteration of the cortex. It is suggested that the condition is mildly contagious, for 9 of the cases occurred in a single ward, 5 in another, and 2 in a third. Salvarsan was very efficacious. It was given in the powder form dusted into the auditory canal, as well as intravenously. In 4 cases complete recovery ensued in from two days to two weeks. It is known that the nowadays comparatively rare condition, noma, is due to Vincent's spirillum, and in 75 per cent. of these cases salvarsan can notably reduce the ulceration. It is probable that not only the spirillum of relapsing fever and syphilis, but also Vincent's spirillum is closely allied to the trypanosomes.

THE EXTINGUISHING OF SMALL PETROL FIRES.

A SMALL petrol fire in the garage or hangar may easily be the beginning of a serious conflagration, and so a simple means for extinguishing the small fire may render valuable service. The British Fire Prevention Committee have recently carried out a series of tests with the view of finding a simple mixture which when thrown on the fire would extinguish the flames. The mixture ultimately found to give the best results was sawdust and bicarbonate of soda, which has advantages over sand and similar materials as an extinguishing medium for small fires. Sawdust would seem to act by floating on the surface of the inflammable liquid, thus excluding the oxygen of the air and smothering the fire. Ordinary sawdust as obtained from sawmills is reported to be the most suitable for the purpose, but it should be free from shavings and chips of wood, while it does not require to be either specially dried or to contain added moisture. The addition of bicarbonate of soda, although not essential, has certain advantages. In the heat of the flame carbonic acid gas is given off from the bicarbonate of soda adhering to the floating sawdust, and accordingly close to the source of the fire. The gas thus given off helps to extinguish the fire. The committee have found that an effective proportion of bicarbonate of soda to sawdust is 10 lb. of the former to 12 lb. of the latter. They recommend that this mixture be kept in a bin holding eight bushels. In regard to the application of the mixture, the committee recommend that in order to be thoroughly effective it should be applied not only in bulk, but rapidly and systematically, the object being to produce what may be termed a lateral "curtain" or scythe effect. Judging from the number of inquiries which have been made on this subject, many of our readers will be glad to hear of this simple device. The committee are careful to add that so far their investigations have been limited to small quantities of inflammable liquids not exceeding two gallons, and the areas over which they were spread did not exceed six feet square. These conditions are generally met with in motor garages and hangars for which the proposed mixture is, in their opinion, applicable and economical.

THE next annual congress of the Ophthalmological Society of the United Kingdom will be held on Thursday, Friday, and Saturday, May 4th, 5th, and 6th, under the presidency of Mr. Walter H. H. Jessop. The meetings will be held at the rooms of the Royal Society of Medicine, 1, Wimpole-street, London, W., and a clinical meeting at the Central London Ophthalmic Hospital, Judd-street, W.C. Members desirous of reading papers, showing cases, or taking part in the discussions, are requested to communicate as soon as possible with Mr. Elmore Brewerton, 84, Wimpole-street, London, W. It is proposed to hold a museum of drawings and pathological specimens during the congress. Those wishing to exhibit should communicate with Mr. Stephen Mayou, 30, Cavendish-square, W.

THE annual Oration of the Medical Society of London will be delivered in the rooms of the society, 11, Chandos-street, Cavendish-square, on Monday, May 1st, at 8.30 P.M., by Sir StClair Thomson, who has taken as his subject "Shakespeare and Medicine." There will be an exhibition of portraits, books, and other objects of Shakespearian interest.

THE HOSPITAL SATURDAY FUND.

THE forty-second annual meeting of the Fund was held at the Mansion House on April 12th under the presidency of the LORD MAYOR, who announced that the income of the Fund during 1915 was nearly £7000 more than that for 1914, probably due to the recognition on the part of the public of the splendid way in which the metropolitan hospitals had succoured the sick and wounded soldiers.

Sir T. VEZEY STRONG, in moving the adoption of the report and balance-sheet, stated that the income for the year was £46,000, the expenses connected with the collection of that sum having been only 7 per cent., as against 30 per cent. in the year of inauguration. The collection included 100,000 pennies.

Colonel Sir ALFRED PEARCE GOULD, K.C.V.O., delivered an address on the Effects of the War on Work in Civil Hospitals. After making a graceful reference to the memory of the late Sir Thomas Crosby, he said that the central and most important factor in any hospital was the medical staff, supported by the nursing staff. To know whether a hospital was a good one or not, one should not look at the building, the site, the subscription list, or the cost per bed, but at the medical and nursing staffs, and ask whether they were doing their work well and whether the full means of carrying it out efficiently were being supplied by the hospital management. The war had drawn away from civil hospitals a certain number of physicians and surgeons, resulting in more work being thrown upon those remaining. Others were devoting a large part of their time to work in military hospitals in and around London. And the younger men—house physicians and surgeons, radiologists, bacteriologists—had been largely swept up by the organisation of the War Office. That serious depletion had been to some extent met by men who had retired from hospital work coming back to it, and only those who had been through that ordeal would know exactly what it meant. In many cases men who had earned their retirement stayed on and bore the burden and heat of the day, and this was supplemented by men who had not hitherto held hospital appointments stepping in and offering their services. The grave situation had very largely been met by the services of medical women. The entrants at the Women's Medical School in London last October were twice as numerous as in the previous October; the new situation had given a great incentive to women to enter the profession. The demand for nurses in this war had been enormous, and he pointed out that nurses had done their utmost during the last decade to make a real profession of nursing, and were very anxious that it should maintain its high position. But their patriotic feeling had led them to admit as helpers those who had not had a nurse's training, and those who knew something of the feeling of trade unionists on labour dilution would be able to appreciate what the concession meant. And he was glad to find that these helpers were doing splendid work. He concluded by references to the serious interference which must take place in medical education and to the enhanced price of drugs, and appealed earnestly for a continued and increased support in this magnificent struggle for the greatest of all causes.

THE WORK OF THE ROYAL FREE HOSPITAL UNIT IN SERBIA.*[1]

BY JAMES BERRY, F.R.C.S. ENG.

As the summer wore on and the long-expected renewal of active hostilities on the Serbian frontier did not take place the number of patients in our hospitals at Vrnjatchka Banja[2] gradually diminished. On August 9th the total number of in-patients was but 180, on Sept. 8th only 167, and of these about one-tenth were civilians. On July 27th a meeting of the heads of the British units then in Serbia had been summoned at Kragujevatz to discuss the situation with Sir Ralph Paget, the British Commissioner. It was then unanimously agreed that the units should stay in Serbia at least a few weeks longer. Our own unit had already received a letter from the Commander-in-Chief (General Putnik), begging us to remain in Serbia. Later, a circular letter from the Crown Prince was sent to all the units, expressing the hope that the day of their departure would be far distant. It was clear that the horrors of the previous winter, due largely to the lack of doctors, nurses, and sanitary material of all kinds, were still fresh in the minds of the Serbian authorities. They were anxious that we should stay as long as possible with them. In the meantime, although not overburdened with work, we found enough to do with general sanitation and with out-patients.

All through the summer our civilian out-patient department was large, men, women, and children coming often from far-distant villages to receive the advice and medicine bestowed upon them chiefly by Dr. Helen Boyle, Dr. Ada McLaren, Dr. Isabel Inglis, and others, who did admirable work in this sphere of usefulness. The most striking feature of this civilian practice was the great prevalence of all forms of tuberculosis and of diphtheria. The inveterate Serbian custom of living in stuffy, overheated, and ill-ventilated rooms—a custom by no means limited to the poorer classes—is doubtless responsible for the ravages of tubercle in this unfortunate country. The insanitary conditions found in and around most Serbian cottages accounted fully for the prevalence of diphtheria.

Some of the younger patients whom for various reasons we admitted to our wards vomited or passed per anum as many as 50 round worms; nearly every child had at least one round worm. Tapeworms we saw but seldom. The extraordinary prevalence of round worms among both children and adults is doubtless explained by the open and polluted springs and wells from which the vast majority of the rural population obtain their drinking-water.

Renewal of Active Hostilities.

Towards the end of September came the news of Bulgaria's mobilisation. All passenger traffic on the railways was stopped. Some of us who were at Nish at that time saw thousands of troops with guns and stores of all kinds being rushed through to the Bulgarian frontier. At Vrnjatchka Banja day and night troop-trains could be heard running down our valley of the Western Morava on their way to the Eastern front. On Sept. 30th a small party of us had occasion to go to Kragujevatz, the military headquarters and seat of the Arsenal. We arrived just in time to see the end of an Austro-German aeroplane raid. Wild excitement prevailed. A German aeroplane had just been brought down in the centre of the town and all Kragujevatz was jubilant. The mangled and scorched bodies of the unfortunate airmen brought home to us very vividly the horrors of war. The remains of the aeroplane, which we inspected at the arsenal, showed the name of a Stuttgart maker. Early on the following morning we were roused by the sound of fresh firing, and were interested spectators of another air raid in which many bombs were dropped, several civilians and one Austrian prisoner being killed. One bomb fell without exploding in the soft ground of the Stobart camp, at which we were staying, and another did much damage to their stock of marmalade, and, by a few feet, just missed killing a nurse. The object of the raid was evidently the arsenal, into which two or three bombs were actually dropped. A Serb workman was killed, and a couple of bullets penetrated a large petrol tank, but otherwise no harm was done. A good account of this raid has been published by our engineer, Mr. Jan Gordon,[3] who was himself in the arsenal with our motor-car when the bombs fell.

On Oct. 8th a visit to Nish showed the town gaily decorated with flags in excited anticipation of the arrival of French troops who were expected from Salonica on the morrow, but who never came. Crowds of refugees were coming in from Posharevatz, which had just been heavily bombarded from the air. No one seemed to know whether the line from Salonica was still open or not. Among the officials, both Serb and foreign, pessimism was very marked, and not a few indignant remarks were heard about the Allies who had "deserted" Serbia in her time of need. There was among the people, and to a certain extent among the officials, a strong feeling that Serbia, who in the earlier stages of the war had done so much for the allied cause, by decisive victories over the Austrians, should not have been left single-handed to repel a simultaneous invasion by three nations. Although necessarily ignorant of the military reasons which forbade the granting of much-needed help to the sorely tried little nation, we could not help wondering whether these criticisms were not perhaps to some extent justified.

On Oct. 8th the British Commissioner informed us that it was the wish of the Serbian military authorities that the British units should withdraw if the Serbian army found it necessary to retreat, as it was expected they would. By so doing it was hoped that their personnel and stores would be preserved for future service, and they would obviously be of more service both to Serbia and to the allied cause than if they stayed on and became prisoners. They were to hold themselves in readiness to take this step when the expected military orders to this effect arrived, which, however, in our case they never did.

Arrival of Wounded.

Two days later, freshly wounded began to dribble into our hospitals and we heard tales of severe fighting on the northern frontier. But it was not until the 17th that we received a large batch of severely wounded. Among them were several perforating wounds of the brain and numerous compound fractures of the thigh. All wounds had been inflicted at least two or three days previously and most were already septic. We were struck nevertheless by the care that had been taken in the preliminary dressing and splinting of the patients. Nearly all had been caused by shrapnel bullet, a few by rifle-fire, scarcely any by bayonet. An extensive wound of the frontal lobe with much loss of brain substance was treated by being laid freely open, nearly half the left frontal bone having to be removed with trephine and forceps; a large hernia cerebri ensued, but this gradually receded and in a few weeks the patient made a good recovery and seemed but little the worse for his injury. Another, with a depressed but non-perforating shrapnel wound of the right occipital lobe, was on admission completely blind in both eyes; the depressed bone was removed. About three days later he had recovered his sight so far that he could distinguish and name coins shown to him, and was doing very well indeed. Two days later he suddenly complained of violent pains in the head and died in a few hours. Another man, under the care of my colleague, Dr. J. B. Christopherson at the Drzhavna Hospital, had been shot through the centre of the head of the left humerus; a conical German bullet was extracted from the lower part of the right axilla in the mid-axillary line. The patient made an excellent and speedy recovery, but how the great vessels of the mediastinum escaped injury is difficult to explain. Another man was shot transversely through the centre of the thorax, the bullet passing between

* The official name of the unit was Anglo-Serbian Hospital, but in Serbia it was known as the Berry Mission, having been organised by Mr. James Berry and Mrs. Berry, M.D., who appointed a small committee to continue their work of collecting funds during their absence. As many members of the medical and nursing staff and committee were associated with the Royal Free Hospital, which helped the mission in other ways, we give the name which it usually received.—ED. L.

[1] See THE LANCET, Jan. 29th, 1916, p. 270.

[2] The name of our village or little town is *Vrntse*. As Serbian proper names are always declined, the Baths of Vrntse are *Vrnjatchka* Banja, just as one might speak of Harrogate and "Harrogatian" Baths, if a similar practice prevailed here. Another and formerly better-known place in Serbia, much further south, is Vranje; this also has baths, called Vranshka Banja. There was much confusion of all these names, even by members of the English missions.

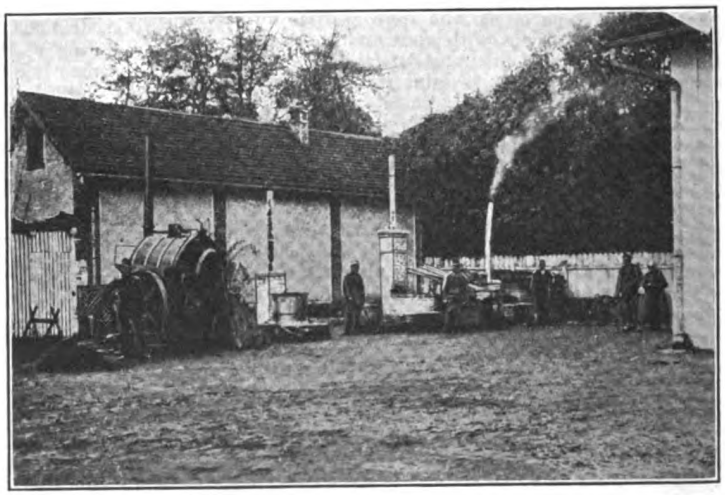
FIG. 1.

Receiving room at the "Terapia" hospital. English nurses with English and Austrian orderlies. Each patient arrived through the window (on the left) and was dressed, shaved, washed, and provided with clean hospital garments before being taken to the ward. By these means all lice and nits were removed before the patient came into the wards, and typhus, although often introduced, never spread to other patients.

the œsophagus and the heart; a left empyema developed. For a time the patient was very ill, but seemed to be on the high road to recovery, when he was transferred to another hospital and we lost sight of him.

On the 15th news came that the Austrians were occupying Posharevatz, Semendria, Belgrade, and Obrenovatz. Also that the Bulgars had penetrated the Eastern frontier at two points, although it was rumoured that they had been driven back again. Major Gashitch, our energetic and esteemed Serb medical director, warned us that we might receive orders to move at very short notice. Packing-cases were brought out by our engineer and made ready for immediate use.

From Oct. 16th till the 18th Vrntse was full of rumours. War on Bulgaria had been declared by the Great Powers, Varna and Bourgas were being bombarded by the Russians, Strumnitza had been occupied by the French, Tsaribrod by the Serbs, the National Bank had been transferred to Prisrend and the military headquarters to Krushevatz. A strange jumble of truth and fiction, but at the time we had no means of separating the one from the other.



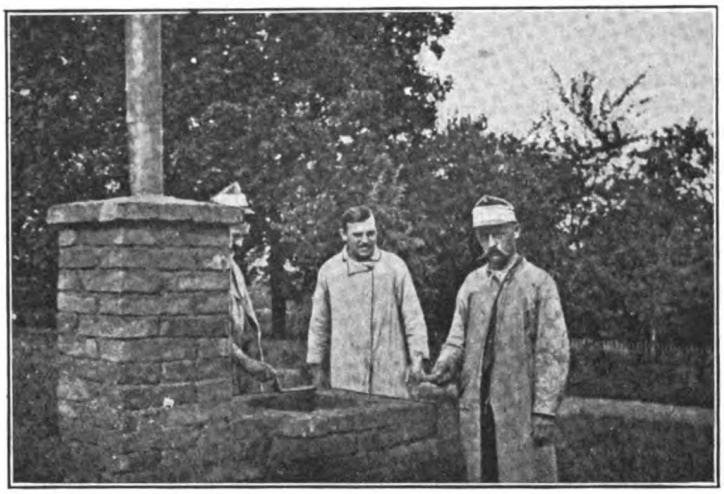
On the 21st a large number of slightly wounded arrived, and as the train which brought them had many severely wounded on board, who went on to the Serb hospital at Chachak, we were indignant at what seemed to us a breach of faith on the part of the military authorities. For months before, when entreated by the Serb military authorities to prolong our stay in Serbia, we had been repeatedly assured, both verbally and in writing, that when fresh fighting began only the most severe surgical cases would be sent to us. On pressing the major for an explanation, we learnt that a secret order had been received that for the present only slightly wounded were to be sent to the foreign missions, as an order for their withdrawal to the south was to be expected at any moment.

On the 27th another trainload of wounded, mostly not very severe cases, arrived, and we were all kept busy. On the 28th important news arrived. Uzhitsa, to the west, at the head of our valley, was being evacuated, and all British missions to the north of us were being withdrawn to the line of the Western Morava; our little town lay some three miles south of this, between Kraljevo and Krushevatz. Kragujevatz, 50 miles (by road) to the north, was being evacuated, the head-quarters staff moving thence to Krushevatz. The seat of government was being transferred to Kraljevo. About this time officials of the public health and some other departments, together with many ex-ministers, sought refuge at Vrnjatchka Banja, the fashionable health resort of Serbia. The place began to be inconveniently overcrowded, and we began to fear shortage of food. The 2nd British Farmers' unit under Mr. Parsons, the Scottish Women's unit under Dr. Alice Hutchison, and several members of the Wounded Allies' Mission under Dr. Apsland arrived, and considerable rearrangement of our hospitals took place. The Farmers, who had been obliged to leave Belgrade very hurriedly during the bombardment, took over our Merkur Hospital and the Scottish Women for a short time had the Atina.

A Difficult Situation.

The British Commissioner now paid us a hurried visit to explain the arrangements he had been trying to make with the Serbian authorities for the withdrawal of the British units to the south or west. Only a very few ox-wagons were obtainable, and it was obvious that most of the units at Vrnjatchka Banja would have to stay and be captured; only individual members, who for one reason or another desired to escape, would have the opportunity of making their way mostly on foot across the mountains to the Adriatic. Three of our unit, together with several of the British Red Cross unit (mostly English orderlies), went off together under the leadership of Mr. Gordon. The adventures and trials which they met with on their difficult trek to S. Giovanni di Medua, have been graphically told by Mr. and Mrs. Gordon in their

FIG. 2.



The yard of the "Drzhavna" hospital, showing (right to left) hot-water boiler, destructor for dirty dressings and other refuse, tank for boiling infected clothing, and a "Thresh" disinfector recently arrived (September, 1915) from England. The tanks were made by the local tinsmith, and the brickwork built by Austrian orderlies. (From a photograph by my colleague, Dr. J. B. Christopherson.)

book, already mentioned. The numbers of our unit remained, however, at the average strength of 25, having been reinforced by the addition of the British chaplain and two refugee ladies from Belgrade and Nish.

On Nov. 1st all the Austrian prisoners except four were withdrawn from our hospitals and replaced by 16 Serbian youths with no personal knowledge whatever of hospital work. On the same day our Serbian military head, although giving no direct order, strongly advised us to withdraw also, abandoning all our stores and personal luggage. Dr. Charles Mack, an American doctor, kindly consented to take charge of the hospital if we decided to do so, and the great majority of our members were anxious to go. We knew of a direct short route across the mountains to Rashka, a place which Mrs. Berry and I had visited many years before, and thence it would have been possible to get across *viâ* Novi Bazar and Berane to the Adriatic. But this would have meant walking the whole way, carrying provisions for at least a fortnight. For this it was essential we should have at least three or four horses to carry food and blankets. We were quite determined not to attempt the ordinary route *viâ* Kraljevo and the long, narrow Ibar gorge, which was also known to us, as it was the main route by which the Serb army was retreating, and was likely to be choked by refugees. Our hesitation, which lasted for a few hours, was ended when we found that the horses we had expected to obtain were not available.

On the following day all our Austrian prisoners were restored to us, and the contingent of Serbian youths, who in the meantime had been washed and cleared of lice, in their turn withdrew. A week of considerable anxiety ensued. Again nearly all the Austrian prisoners were taken away, a few only, who desired to remain with us, being allowed to do so. They made their way over the mountains in front of the retreating Serbian army, and we fear that many must have perished in the severe cold that set in some ten days later. Day by day the sound of distant cannonade became louder and louder as the Austro-German forces approached. Rumour said that a stand would be made in our valley at Trstenik, a narrow place some three miles to the east of us. It was said that the digging of trenches had actually begun. It seemed probable that we should find ourselves in the very centre of a battle. Late in the evening of the 6th a violent explosion, which shook the building, caused some of us to exclaim, "Here is the first shell!" But it was caused by our own people blowing up the great bridge of Trstenik. Our Serb commissaire at the Terapia had sought safety in flight, but the Austro-Serbian one at the Drzhavna, M. Milutin Jovanovitch, remained with us and rendered invaluable service. Our wood-supply gave out, and as no more was forthcoming we began cutting down the trees in the grounds of the Terapia.

FIG. 3.

Austrian orderlies building a destructor at the "School" hospital.

Entry of the Enemy.

Early on Nov. 10th a Hungarian lieutenant with half a dozen soldiers arrived, went all over the hospital, asked for a complete list of our personnel, paid us a few compliments on the state of our hospital, put an armed sentry at the gate and departed. In the next few days we had numerous Austro-Hungarian visitors at the hospitals — generals, colonels, a count, and finally Prince Lobkovitz, who took command of the whole district. Colonel Dr. Pick was in charge of all the medical arrangements, and his first act was to confirm the appointment of the heads of our unit, saying he did not wish to interfere in any way with our management of the hospitals and giving us the necessary Austrian authority to continue our hospital work under his nominal supervision. He consulted freely with us and Major Gashitch as to the best means of rearranging the medical work at Vrnjatchka Banja. The Atina was given over for a short time to another English unit, our *baraque* was evacuated and then the school, the latter being quickly filled with crowds of frost-bitten Hungarians returning from the mountains, very severe cold having set in on the 17th. Our own hospitals were now reduced to two, the Terapia and the Drzhavna. Both were overcrowded with Serb wounded; at the former patients overflowed into the corridors, where we put them on improvised trestle-beds and mattresses. The evacuation of the slighter cases was then rapidly carried out, and as frost-bitten Hungarians continued to pour into the town we were asked to admit some of them for whom no other accommodation could be found. This we naturally consented to do. The Medical Director-General of the Austrians in Serbia visited us, and I overheard him telling another officer that all members of the missions would be interned until the end of the war. This was clearly a contravention of the Geneva Convention, and in all discussions with the Austrians on this subject I continued to point this out. We were much surprised to find how little was known of this Convention by all the Austro-Hungarians with whom we came into contact. The best informed was Captain Dr. Otto Panczél, an elderly Hungarian, who before the war had practised as a civilian surgeon at Pancsova and who became our medical commandant after Colonel Pick's departure. To his courtesy, practical good sense, and kindly feeling towards us we were much indebted during our three months under his charge. I cannot refrain from relating an incident which illustrates the curious ideas about English government which are prevalent even among intelligent and well-informed Hungarians. After a long conversation one day with him on the subject of the politics and history of Hungary, he said suddenly, "Well, you English treat your colonies so badly!" "How so?" said I. "Well, you do not allow them to buy or sell except with the mother country," was his answer, and nothing that I could say would move him from his fixed belief that such were the trade relations between England and her colonies. Equally surprising ignorance about circumstances nearer home was displayed by another Hungarian doctor of good family and education, who made to me the common but ridiculous assertion that "the Serbs had killed the Austrian Archduke." He seemed much interested and surprised to learn that Cabrinovitch Prinzip and the other assassins were *Austrian* Slav subjects and not Serbs as the Austrians endeavour to make the world believe.

With regard to food, we fared, on the whole, fairly well. The Austrians allowed us daily rations, which included a little meat; bread varied in quantity from half a loaf per head when it was abundant to one-fifth when it was scarce, as it often was. Besides these we had small quantities of tea, coffee, sugar, and lard, and various other things. A scale of prices was arranged and the peasants were obliged to bring eggs, milk, and other provisions to a central office, whence they were distributed among Austrians, English, and Serbs. Had we been wholly dependent upon the Austrian rations we should have fared

badly, but fortunately our own food stores were by no means exhausted and we had laid in a considerable stock of flour, rice, and live poultry before the invaders arrived. With these stores the enemy never interfered although they occasionally threatened to do so.

On Feb. 18th we were allowed to depart under the charge of a couple of Hungarian guards, who however, behaved towards us rather as couriers than as gaolers, and treated us with the greatest friendliness and courtesy. We travelled viâ Belgrade, Budapest, and Vienna, to Bludenz on the Swiss frontier, where we were detained nine days, to ensure that any military news that we might bring from Serbia should be stale. We reached Zürich on March 2nd, and thence came home viâ Pontarlier and Paris, the French military authorities giving us free passes through France and treating us with the utmost respect and courtesy.

REPORT OF THE COUNTY MEDICAL OFFICER OF HEALTH AND SCHOOL MEDICAL OFFICER OF LONDON FOR 1914.

(*Concluded from p. 834.*)

PART II.—EDUCATION.

APPRECIATIVE reference has frequently been made in these columns to the coördination of the Public Health and Education Departments which was achieved by the London County Council in 1911. The experience of another complete year as to the working of the new system is now available.

In the course of the year 1913 inquiry was made by the Board of Education into the operation of the Council's scheme of medical inspection and treatment. In a letter reproduced in the medical officer's report for that year the Board suggested some modifications of the scheme. On certain important points, however, the Council's reply had not been agreed upon in time to allow of its appearance in the report for 1913, then almost ready for press. The reply will, however, be found in full at pp. 83–5 of the present volume. The question of the medical staff, as regards its numerical strength, duties, and permanency, was already engaging the Council's attention at the date of receipt of the Board's letter. As a result the duties of the assistant school inspectors have been rearranged, so that their services are now utilised for the whole field of public health work. Moreover, the organising staff has been increased, a definite proportion of its members being allocated to the Public Health Department. Additional facilities for nursing treatment have also been secured, and arrangements have been made that the doctor in charge should be satisfactorily informed respecting the antecedents of children presented for treatment.

In spite of unforeseen difficulties due to war conditions, by which progress has in some degree been retarded, it is encouraging to realise that the arrangements above specified are already in actual operation. On the other hand, considerable disturbance of staff routine has unavoidably taken place. In the treatment centres and hospitals many changes of personnel have occurred, thus interfering to some extent with continuity of method. Owing to the absence on military duty of the permanent school doctor, it has at times been necessary to carry on the work with the aid of temporary substitutes. Inconvenience has also arisen from inevitable changes in the nursing staff. In these circumstances it will be necessary to await the return of normal conditions before a reliable estimate can be formed of the value of the rearrangements hitherto effected.

Medical Inspection of School Children.

In the earlier months of 1914 the work of inspection was carried out, in accordance with the suggestions of the Board of Education, by 35 assistant medical officers under the direction of 5 divisional chiefs. On the outbreak of war several of these officers were called up for military duty, their places being generally filled by medical practitioners devoting part of their time to the work. This inspecting staff was assisted by 106 certificated nurses, who prepared the children for examination and helped in the weighing and measuring processes and in the testing of vision. In the course of the year more than 294,000 children were medically examined, and of these about one-third were found to need treatment. Comparing the results of this examination with those of the two preceding years a gratifying amendment was observed. Steady improvement in cleanliness and neatness was manifest, reflecting great credit on the school nurses, the head teachers, and the workers of the Care Committee. In accordance with the regulations of the Board of Education examination is required of all *entrants* and *leavers*, and in addition an intermediate group of children aged 8–9 years are regularly examined. Consequently there are now three sets of complete records, and the results of inspection in the several years can be readily compared. The term "entrant" is limited to infants under 6, the term "leaver" to children of 12 years and upwards. At the time of inspection the mother is invited to be present. A representative of the Care Committee is likewise asked to attend in order to secure that each child shall receive the medical treatment prescribed. Experience proves that, although starting school-life on an equality with boys, the girls on leaving show excessive tendency to defects of eye and heart, as well as a greater liability to anæmia and to nervous diseases. These facts suggest that girls for the most part lead a less healthy home-life than their brothers. At the time of medical inspection the height and weight of children are recorded. They are classified as to condition of clothing, state of nutrition, cleanliness of head and body, and state of teeth. The averages are said to be very constant. It is noteworthy that entrants are generally cleaner than older children, but that girls, in consequence of wearing long hair, more frequently suffer from dirty and verminous heads than boys. In regard to cleanliness of body, however, the girls appear to advantage. The record of steady improvement during the three years as regards the cleanliness of the children and the sufficiency of their clothing is the most encouraging feature of these inspections. Although it is to be deplored that even now the heads of only 67 per cent. of the girls are completely free from traces of vermin, it must be remembered that ten years ago instead of 67 per cent. being clean, in those days over 67 per cent. were verminous.

Adenoids and enlarged tonsils.—The proportion of children now found thus affected is less than formerly. The reduction is greatest at the higher ages, a fact which may be accepted as an indication that present facilities for treatment are playing an important part in improving the health of school children.

Enlarged glands of the neck.—Considerable improvement is reported under this head also. The percentage of children thus ailing fell from 10·5 in 1913 to 8·8 in the recent year, and only 1 in 20 of these was considered sufficiently ill to require operative interference.

Disease of thyroid gland.—Considerable attention has lately been directed to abnormalities of this gland, especially in those cases in which there exists deficiency of secretion, leading to retardation of mental and bodily growth, and even to idiotcy. The effects of over-action of the gland in adults, constituting exophthalmic goitre, are well known, but to the beginnings of this condition in children little attention has hitherto been paid. Dr. Louis Leipoldt, a former member of the staff, has carefully investigated this question. Out of 5000 children examined he found 52 cases in which symptoms of this over-action were detected. Of these 52 children not fewer than 42 presented definite evidence of septic absorption, either from carious teeth, otorrhœa, or inflamed tonsils. He refers to the striking improvement effected by dental treatment in certain of these cases—the thyroid enlargement disappeared and the usual nervous symptoms abated. Dr. Leipoldt's investigations show that undetected septic conditions in childhood sometimes produce far-reaching ill-effects. They furnish additional reasons for inducing parents to obtain treatment for all children found defective in this respect.

Medical and Dental Treatment.

During the last three years the facilities provided in London for the medical treatment of school children have been materially increased. For all classes of ailment treated under the Council's scheme the "centres," including hospitals, at the end of the year numbered 42, providing for 98,976 children, as against 34 centres for 84,359 children at the end of 1913. Owing chiefly to the great demand

for dental treatment the requirements of the scheme have grown to unexpected proportions. For the year ended April, 1915, out of 125,000 cases attended to more than half were for dental defects. The county medical officer reports favourably of the treatment scheme. The attendance of the children has been generally good. Difficulties have, not unnaturally, been encountered in persuading parents to accept treatment for their children, but in order to overcome them two well-devised measures have been adopted during the year. The first measure provides that time spent at a school treatment centre shall be regarded as "school attendance." This provision at once removes a difficulty felt by teachers as well as parents, who are obviously interested in securing regularity of attendance at school. The second measure enables parents and children visiting treatment centres to travel any distance in a tramcar at the rate of ½d. for each person. The average course of treatment entails three journeys to and from the hospital. Assuming that the parent accompanies the child on each occasion, the total number of journeys would be 12, and if the ordinary fare per journey be 1½d. the total saving to the parent as a result of this concession would be 1s. This arrangement is reported to be appreciated generally by the parents, although as yet it is too early to speak confidently of the effect of the plan in encouraging parents to accept medical treatment for their offspring.

"Following-up": Reinspections.—It is evident that considerable increase in the work of following-up must be involved in every material extension of a treatment scheme. Fortunately the Council has received valuable help from a large body of voluntary workers, by virtue of which each group of schools is now provided with its own "Care Committee." Each school Care Committee is assisted by a staff of "organisers" by whose praiseworthy activities, in connexion with medical work, the success of the Council's treatment scheme has been ensured. Among various ways in which the Care Committee is helpful to the education authority in its oversight of school children the following may be noted: Attending at the medical inspections to explain to mothers the directions of the doctor; advising the parent as to how to secure treatment for her child; home visiting to secure that continuous treatment shall be maintained; arranging for the provision of food for necessitous children, and for the admission of suitable cases to convalescent homes or hospitals. During the year 84,500 reinspections of defective children were made. The results show that about half of the children found defective at the first inspection had commenced to receive treatment by the end of the first six months, and almost a quarter of the remainder after a further six months. In cases of ear, nose, and throat trouble and of dental defects difficulty was at first experienced, but this is steadily diminishing. The success of the Council's scheme is shown by the ascertained fact that children are more rapidly and satisfactorily dealt with under that scheme than by other methods of treatment.

Government grants.—By the regulations of the Board of Education it is provided that local authorities can now receive grants in respect of medical inspection as well as of medical treatment and work ancillary to treatment. The amount received for the year 1913 was £31,191, or 48 per cent. of the total expenditure on these services. For the year 1914 the amount was £38,149. Particulars of the conditions relating to the grants are contained in the letter of the Board of Education, which is appended to the present report.

Open-Air Schools.

Both the open-air schools established by the Council have been in full operation throughout the winter months. The excellent results of former years have been fully maintained. Further accommodation in schools of this type is needed in all parts of London, but particularly in the districts north of the Thames. The increasing efficiency of open-air treatment in the case of tuberculous children is beginning to make itself felt in both the schools of the County Council. Children are now returning thither from sanatorium treatment who require education on the open-air system, in order to maintain the improvement already accomplished in their physical condition.

Birley House and Shooter's Hill Schools.—The work in these schools has been continued on the same lines as in past years, and with equally good results. At Birley House all the children were re-examined in March, 1914, and 48 of them were returned to their former schools, while 38 were retained for another year, and were joined by 60 fresh pupils selected by the school medical officer as suitable for education there. At Shooter's Hill two bungalows are provided for use in stormy weather, but where possible classes are held in the open air. Three hours and a half are devoted daily to study, including manual work, and nearly two hours to sleep—in summer immediately after dinner. In accordance with the special war provisions the children are dismissed to their homes at 4 P.M. The school is open continuously throughout the winter, and the open-air principle is adhered to, the windows being kept widely open, whilst good fires are maintained in the bungalows. During the year the average attendance was 100, drawn chiefly from readily accessible districts. At the resumption of work in April the places of 26 old pupils were filled by 32 newcomers.

Kensal House Tuberculosis School.—The number of children on the roll here average 95. Since the opening of the school 230 children have been admitted, of whom 29 were allowed to engage in suitable work away from school; 15 returned to elementary schools, 12 entered convalescent homes, and 36 were excluded on medical grounds. The results of the year's work are distinctly encouraging: there is a marked improvement in the children with very few exceptions, which may readily be accounted for. The joiners' class has been successful, and so has the swimming class, the children attending the latter being specially selected by the medical officer. The dispensary authorities have provided free dinners and other assistance in cases of extreme poverty.

In concluding a brief review of Dr. W. H. Hamer's third annual report as medical officer of health and school medical officer we would express our sense of the high value of his work in both capacities in spite of inevitable difficulties resulting from war conditions. Little but the leading features of this instructive volume have been noticed here, but we confidently recommend the study of the report as a whole to our readers.

NATIONAL LEAGUE FOR PHYSICAL EDUCATION AND IMPROVEMENT.—A course of lectures on the Care of the School Child will be held at the London Day Training College, Southampton-row, on Wednesdays from 5.30 to 6.30 P.M., from May 3rd to July 19th. Particulars may be obtained from the Secretary, 4, Tavistock-square, W.C.

ROYAL COLLEGE OF PHYSICIANS OF LONDON: ELECTION OF PRESIDENT.—A Comitia was held on April 17th, Dr. Frederick Taylor, the President, being in the chair. The President delivered the usual address, in the course of which he referred to the honours conferred on Fellows, Members, and Licentiates during the year, including those received in connexion with medical service in the war. He also mentioned the lectures delivered in the College, and the medals, prizes, and scholarships which had been awarded. Reference was also made to the report, which had been adopted by the College, on the duties of medical practitioners in connexion with criminal abortion. He briefly explained the formation of the Central Medical War Committee, of which he had become a member, and also the election of an advisory committee in conjunction with the Royal College of Surgeons of England to advise the Government through the Central Medical War Committee. The President then read obituary notices of ten Fellows who had died during the year—viz., Dr. Henry Lewis Jones, Sir Peter Eade, Dr. David Bridge Lees, Sir Robert Michael Simon, Dr. Robert Maguire, Dr. George Allan Heron, Dr. George Oliver, Sir William Richard Gowers, Dr. Henry Charlton Bastian, and Dr. Thomas Colcott Fox. The President then thanked the College for the courtesy and assistance extended to him by the College officers and Fellows. Sir William Church proposed a vote of thanks to the President for his services during the past year, with a request that the address might be printed. This was duly carried, and the President vacated the chair. The election of President then took place, and Dr. Frederick Taylor was re-elected by a large majority. The Senior Censor (Dr. Percy Kidd) presented him with the insignia of office, and the President gave his faith to the College and thanked the Fellows for having re-elected him. Dr. Norman Moore was re-elected the representative of the College on the General Medical Council. A report from the committee of management was received and adopted recommending that the Leighton Park School, Reading, should be added to the list of institutions recognised by the Examining Board in England for instruction in chemistry, physics, and biology. The President then dissolved the Comitia.

PARIS.

(FROM OUR OWN CORRESPONDENTS.)

The Value of the Metal Helmet.

THE metal helmet is one of the best means thought of latterly for the protection of our soldiers. Nearly 4,000,000 of them have been distributed. Dr. Roussy, of the medical bureau at the Place de Paris, has established statistics to see in what measure the wearing of them has afforded protection and the degree of gravity of the wounds. For 100 wounds received on the rest of the body before the use of helmets there were 8·5 wounds of the cranium, now since they have been worn the proportion is 16·82 per cent., but all the combatants had not worn them at the time the statistics were collated. The results indicate (1) that when the percentage was only 8·5 a large number of men shot in the head (without helmet) have been mortally wounded, dying on the field of battle or in hospital; and (2) that when the percentage was 16 82 the helmet has afforded protection, and the number of wounded men cured or convalescent has been much larger. Also the gravity of the injuries has been far less. I need hardly indicate the fatal nature of head wounds, characterised as they are by coma, blindness, deafness, various paralyses, amnesia, and vertigo, and then by comminuted fractures with loss of cerebral substance, necessitating one or several trephinings which entail large losses of osseous tissue. By the use of the helmet these cranial wounds are rendered relatively of little gravity. Many of the symptoms noted in the cases of those without helmet were not present when helmets were worn, and the patients recovered in little time, and completely, very often without trephining. In a great number of cases the projectile was stopped by the resistance encountered and remained embedded in the metal, or made only a contused wound in the scalp and subjacent external table, or was arrested in the cranial bone without traversing it, or finally the projectile had deviated, thus diminishing the gravity of the wound. All the combatants are convinced of the protective rôle of the helmet, and their confidence increases its value, for it renders them careful to assume it.

Ingenious Apparatus for Maimed Arms.

Professor Laveran has presented to the Academy of Sciences some mechanisms as ingenious as they are practical. By their aid maimed arms have the natural appearance of the member restored, as well as much of their previous ability. The mechanisms, invented by Professor Amar, can, by the movements of the thorax, bring into action a spring and some steel wires. By this means are recovered to a great extent the former movements, even the most delicate, of the forearm and fingers, the latter being replaced by aluminium substitutes. Moreover, there are two categories of apparatus: those for heavy work, permitting the return of the men to their previous occupations; and others, "universal hands," for movements of dexterity the most diverse. Men have been enabled to play the violin, light cigarettes, and give change. The aluminium hand weighs only 350 gm., and with a glove on has quite the usual appearance. The whole apparatus weighs only 500–1100 gm. (the entire arm).

Treatment of Wound Infection.

Strong testimony to the efficacy of wound disinfection by Dakin's fluid, a solution of hypochlorite of soda, is given by Dr. Uffoltz, Directeur du Service de Santé of the 35th French Army Corps, after six months' systematic use in the field. Known as the Carrel method, from its originator Dr. Carrel of the Rockefeller Institute, its principle consists in immediate antiseptic application to the wound. The solution employed, which contains 0·5 to 0 6 per cent. of sodium hypochlorite, is readily prepared by dissolving 140 gm. of dry carbonate of soda (or 400 gm. of the crystallised salt) in 10 litres of tap-water and adding 200 gm. of chloride of lime. The mixture is well shaken, and after half an hour the fluid is siphoned off, and filtered through cotton-wool; 40 gm. boric acid are then added, and the solution is ready for use; it does not keep for more than a week. It is neutral and non-irritating. Applied within six hours of the receipt of the wound it brings about in most cases a localisation of the infective process and its early extinction. Rapid transport of the patient to the ambulance station is essential; the wound is then cleansed by extraction of foreign bodies, splinters, &c. (no sponging allowed), and the fluid thoroughly applied by irrigation. This may be done by instillation of 5 c.c. of the fluid into each tube every two hours or, better, by continuous instillation, drop by drop. Wounded men should not be evacuated from the ambulance station until complete sterilisation of the wound and application of a sterile dressing has been carried out. I am led to point out that this treatment is not a novelty, as is suggested in the lay press. The use of the fluid was discussed last summer at the Academy of Sciences, and in the *Archives de Médecine et de Pharmacie Militaires* for January the satisfactory results in 130 cases of wounds of all degrees of severity are described in detail. The chief points are: absence of both general and local inflammation, of pain, and (to a great extent) of fever; rapid recovery of appetite and of sleep; comfort of the patient; absence of the usual characteristic odour in the wards. The same issue of the *Archives* also contains an exhaustive discussion on bone infection, the result of gunshot wounds, by M. Trutié de Vaucresson, médecin major de 1re classe. The conclusions arrived at are that these *infections tardives* are really a traumatic osteomyelitis, the clinical manifestation being a simple fistula leading to the interior of a much-enlarged bone, in which exists (as revealed by radiography) an abnormal clear space. Pathologically, the fistulous cavity contains necrosing bony tissue in the centre, surrounded by a zone of rarefying osteitis, outside which again is a concentric defensive layer of condensing osteitis, which limits the infection. The treatment consists in free opening of the cavity and removal of all diseased bone, followed by infrequent dressings, well rammed in to ensure healing from the bottom of the wound. Recovery is said to be slow, but sure. It would probably be accelerated if the cleared-out cavity could be closed up with complete asepsis.

Night Blindness in Soldiers.

M. Weekers has reported to the Academy of Medicine that night blindness is now occurring among soldiers. The affected soldiers see very well during the day, but the vision is affected towards evening and especially night, to the extent of the men being completely disorientated. In these subjects, of whom the number is somewhat large, there exists no other functional trouble but insufficient retinal adaptation. It seems that the principal cause of the condition is nervous exhaustion (over-exertion). For hemeralopia hepatic opotherapy in various forms has been recommended, but this treatment appears hardly justified in the present cases. Here above all should be adopted a treatment directed to the cause, holding in view military needs. For the dazzling due to long exposure to strong light yellow glasses are to be worn during the day. It is well to take precautions against ocular fatigue arising from external inflammation or refractive errors. Finally, these men should have a strengthening régime and very varied diet. Exceptionally it may be possible to admit them to hospital for a time to obtain rest and receive a special régime, to which may be added iron or arsenic medication. But M. Weekers is of opinion that hemeralopia alone cannot justify sending these men to the rear.

Against Tuberculosis.

A society has just been constituted in Paris, under the name of the Comité Central d'Assistance aux Militaires Tuberculeux, whose object, inspired alike by benevolence and social hygiene, is to help soldiers invalided owing to tuberculosis since the war began. The action of the central committee will extend over the whole country, and will be exercised in coördinating the efforts of departmental committees, and in furnishing them with indications useful in accomplishing their mission. The tuberculous subject occupies the first rank in the general mortality. It is urgent to create a movement of opinion and to awaken sleeping energies towards both the prevention of tuberculosis and its cure. It is necessary to give to all classes of society practical education on the disease so as to delimit the evil. Also the law should require the tuberculous to profit by the assistance offered by the offices of social hygiene.

April 15th.

VITAL STATISTICS.

VITAL STATISTICS OF LONDON DURING MARCH, 1916.

In the accompanying table will be found summarised complete statistics relating to sickness and mortality in the City of London and in each of the metropolitan boroughs. With regard to the notified cases of infectious diseases, it appears that the number of persons reported to be suffering from one or other of the 10 diseases specified in the table was equal to an annual rate of 5·6 per 1000 of the population, estimated at 4,310,030 in the middle of last year; in the two preceding months the rates were 6·5 and 6·0 per 1000 respectively. The lowest rates last month were recorded in Hammersmith, the City of Westminster, St. Marylebone, Holborn, and the City of London; and the highest rates in Finsbury, Shoreditch, Bethnal Green, Stepney, Battersea, and Greenwich. The prevalence of scarlet fever showed a further decline last month; this disease was proportionally most prevalent in Finsbury, Shoreditch, Bethnal Green, Wandsworth, Deptford, and Greenwich. The Metropolitan Asylums Hospitals contained 1735 scarlet fever patients at the end of last month, against 2431, 2157, and 1956 at the end of the three preceding months; the weekly admissions averaged 208, against 248, 249, and 210 in the three preceding months. The prevalence of diphtheria showed a considerable decline last month; among the several metropolitan boroughs the greatest proportional prevalence of this disease was recorded in Shoreditch, Bethnal Green, Stepney, Bermondsey, and Battersea. The number of diphtheria patients under treatment in the Metropolitan Asylums Hospitals, which had been 1491 and 1538 at the end of the two preceding months, had declined again to 1417 at the end of last month; the weekly admissions averaged 160, against 198 in each of the two preceding months. Enteric fever was rather less prevalent than it had been in other recent months; the 38 cases of this disease notified last month included 7 in Southwark, and 3 each in Islington, Bethnal Green, Stepney, Battersea, and Wandsworth. There were 46 cases of enteric fever under treatment in the Metropolitan Asylums Hospitals at the end of last month, against 44 and 50 in the two preceding months; the weekly average number of new cases admitted to these hospitals, which had been 7 in each of the two preceding months. was again 7 last month. Erysipelas was proportionally most prevalent in Paddington, Shoreditch, Bethnal Green, Poplar, Southwark, Camberwell and Deptford. The 34 cases of puerperal fever notified during the month included 4 in Poplar, and 3 each in Kensington, Fulham, Bethnal Green, and Lambeth. Of the 68 cases of cerebro-spinal meningitis 7 belonged to Lambeth, 5 to Shoreditch, 5 to Southwark, 5 to Wandsworth, and 4 each to Kensington, Fulham, Islington, Hackney, Finsbury, and Bethnal Green; the 4 cases of poliomyelitis belonged respectively to the City of Westminster, St. Marylebone, Hampstead, and Hackney.

The mortality statistics in the table relate to the deaths of persons actually belonging to the several boroughs, the deaths occurring in institutions having been distributed among the boroughs in which the deceased persons had previously resided. During the five weeks ending April 1st, the deaths of 7497 London residents were registered, equal to an annual death-rate of 18·1 per 1000; in the three preceding months the rates were 17·3, 13·5, and 14·5 per 1000 respectively. The death-rates last month ranged from 13·8 in Hampstead, 15·0 in Wandsworth and in Lewisham, 15·1 in Woolwich, 15·2 in Fulham, and 15·3 in Stoke Newington, to 21·3 in Bermondsey, 21·6 in Chelsea, 21·8 in Southwark, 23·5 in Shoreditch, and 25·2 in Finsbury. The 7497 deaths from all causes included 438 which were referred to the principal infectious diseases; of these, 91 resulted from measles, 18 from scarlet fever, 80 from diphtheria, 159 from whooping-cough, 8 from enteric fever, and 82 from diarrhœa and enteritis among children under 2 years of age. The 91 deaths from measles showed a decline of 316 from the corrected average number in the corresponding period of the five preceding years; this disease was proportionally most fatal last month in Hammersmith,

ANALYSIS OF SICKNESS AND MORTALITY STATISTICS IN LONDON DURING MARCH, 1916.

(Specially compiled for THE LANCET.)

CITIES AND BOROUGHS.	Estimated civil population, 1915.	NOTIFIED CASES OF INFECTIOUS DISEASE.												DEATHS FROM PRINCIPAL INFECTIOUS DISEASES.									Deaths from all causes.	Death-rate per 1000 living.

* Including membranous croup.

Islington, Finsbury, Stepney, and Deptford. The 18 deaths from scarlet fever were 3 below the corrected average, and included 7 in Islington, 3 in St. Pancras, and 2 in Bethnal Green. The 80 fatal cases of diphtheria were 21 above the average number. The greatest proportional mortality from this disease was recorded in Shoreditch, Poplar, Southwark, Bermondsey, Battersea, and Greenwich. The 159 deaths from whooping-cough were 6 in excess of the corrected average number; this disease was proportionally most fatal last month in Chelsea, Shoreditch, Southwark, Wandsworth, Greenwich, and Woolwich. The 8 fatal cases of enteric fever slightly exceeded the corrected average number, and included 2 in Lewisham and one each in Fulham, Islington, Hackney, Southwark, Wandsworth, and Greenwich. The mortality from diarrhœa and enteritis among children under 2 years of age was proportionally greatest in Fulham, St. Marylebone, Holborn, Shoreditch, Stepney, and Bermondsey. In conclusion, it may be stated that the aggregate mortality in London last month from the principal infectious diseases was 45 per cent. below the average.

THE SERVICES.

ROYAL NAVY MEDICAL SERVICE.

E. B. Kelley has been entered as a Surgeon for temporary Service in His Majesty's Fleet.

ROYAL ARMY MEDICAL CORPS.

Temporary Major W. T. Prout, C.M.G., to be temporary Lieutenant-Colonel.

The undermentioned Majors to be temporary Lieutenant-Colonels whilst commanding Casualty Clearing Stations:—R. F. Ellery and R. J. Cahill.

The undermentioned are granted temporary rank whilst commanding Field Ambulances:—As Lieutenant-Colonels: Major W. M. B. Sparkes and Major J. G. Bell. As Majors: Captain W. E. Marshall and temporary Captains G. D. McLean and N. K. Wilson. As Captain: Temporary Lieutenant F. D. Johnson.

Major (temporary Lieutenant-Colonel) S. E. Lewis relinquishes his temporary rank on ceasing to command a Field Ambulance.

Temporary Captain H. B. Maunsell relinquishes his commission.

Temporary Captain W. P. Hogg relinquishes his commission on appointment to the Indian Medical Service.

The undermentioned are granted temporary rank whilst employed at the Northamptonshire War Hospital:—Lieutenant-Colonel W. Harding and Major F. J. Stuart.

A. D. Vardon, late Captain, Banffshire Artillery, Volunteers, to be temporary Captain.

The undermentioned temporary Lieutenants relinquish their commissions:—T. A. Brandon and W. G. S. Thomson.

SPECIAL RESERVE OF OFFICERS.

Royal Army Medical Corps.

Captain (temporary Major) H. G. Trayer relinquishes his temporary rank on ceasing to command a Field Ambulance.

The undermentioned Lieutenants to be Captains:—J. H. C. Walker, M. B. King, R. H. Graham, A. G. Fisher, W. Hunt, and C. McL. West.

TERRITORIAL FORCE RESERVE.

Royal Army Medical Corps.

Captain R. G. Wills, from West Lancs Field Ambulance, to be Captain.

TERRITORIAL FORCE.

Royal Army Medical Corps.

Highland Field Ambulance: Captain G. Davidson to be temporary Major whilst commanding a Field Ambulance. Captain (temporary Major) G. Davidson relinquishes his temporary rank on ceasing to command a Field Ambulance.

Welsh Field Ambulance: J. T. Samuel to be Lieutenant.

London Sanitary Company: J. Griffiths to be Lieutenant.

Supernumerary for service with the Officers Training Corps.—W. Wright to be Lieutenant for service with the Medical Unit of the University of London Contingent, Senior Division, O.T.C.

Attached to Units other than Medical Units.—Surgeon-Major E. G. Stocker, from Wessex Divisional Engineers, and Surgeon-Major V. Graham, from Yorks Light Infantry, to be Majors. Captain W. Marley-Cass relinquishes his commission on account of ill-health. To be Captains: Lieutenants C. W. J. Brasher, W. W. Horton, and H. Smith.

NAVAL MEDICAL COMPASSIONATE FUND.

At the quarterly meeting of the directors of the Naval Medical Compassionate Fund held on April 11th, Surgeon-General G. Welch, R.N., being in the chair, the sum of £60 was distributed among the several applicants.

Obituary.

SIR ALEXANDER RUSSELL SIMPSON, M.D. EDIN., F.R.C.P. EDIN., F.F.P.S. GLASG., D.SC. VICT., LL.D. EDIN., F.R.S.E.,

EMERITUS PROFESSOR OF MIDWIFERY AND DISEASES OF WOMEN AND CHILDREN, UNIVERSITY OF EDINBURGH; CONSULTING PHYSICIAN FOR DISEASES OF WOMEN, ROYAL INFIRMARY, EDINBURGH, ETC.

BY the death of Sir Alexander Russell Simpson another link with the past is gone. His death (as stated in our last issue) in Edinburgh on April 6th, at the age of 80, was the result of a motor-car accident. Born at Bathgate on April 30th, 1835, he was the second son of Mr. Alexander Simpson of that town. After his early education at Bathgate Academy he proceeded to the University of Edinburgh. The system of apprenticeship had not then died out, and he was apprenticed to Professor Goodsir. On Professor Simpson's farewell address at the University in 1905 he gave some reminiscences[1] in which he mentioned that three of his fellow students had been apprenticed similarly to a University professor, and although he had not been helped much, he said, in learning to cure disease, the apprenticeship gave him opportunities that had been a life-long benefit: it had brought him under the spell of a man of genius who was a tireless worker and who sought always what he called "God's truth." Simpson graduated as M.D. Edin. in 1856. He then visited the continent, studying at the Universities of Montpellier and Berlin. It may be mentioned that he was elected President of the Royal Medical Society of Edinburgh while still a student. On returning from the continent he was assistant for seven years to his uncle, Sir James Y. Simpson, who then held the chair of Midwifery in Edinburgh, and whose memory is kept green by his introduction of chloroform as an anæsthetic in 1847. Afterwards he was in practice for five years in Glasgow. This was the period that saw the inception of those vast changes in surgery familiar to all—changes due to Lister's work in conjunction with the use of anæsthesia, which paved the way for the present-day remarkable achievements in all branches of medicine and surgery. Simpson wrote that when he was Syme's dresser he met Lister in Edinburgh, and later in Glasgow, when Lister was professor of surgery there and was making his early experiments in treating compound fractures with carbolised putty in the Glasgow Royal Infirmary. Simpson became F.R.C.P. Edin. and F.F.P.S. Glasg. in 1865. On the death of Sir James Simpson in 1870, he was appointed to the chair of Midwifery, which he held until 1905. He was also physician for diseases of women at the Royal Infirmary, Edinburgh, and to the Royal Maternity and Simpson Memorial Hospital, being consulting physician at the time of his death. He likewise held the post of Dean of the Medical Faculty in Edinburgh.

During the long period of 35 years that Simpson occupied his chair, and notwithstanding the immense advances made, especially in gynæcology, he kept himself abreast even of this department, and was recognised by his colleagues as an able, expert, and successful operator. On his retirement an address was presented to him by students and graduates in the following terms: "You have added so much to the renown of our University in regard to the teaching and advancement of midwifery and gynæcology that, in conjunction with your distinguished predecessor, you have caused the name of Simpson in this department of science to rank worthily alongside that of Monro in anatomy and of Gregory in medicine. This you have achieved not only by your learned contributions to the literature of the subject, containing many and stimulating suggestions, but also by your practice in the perfecting of technique and in the invention and improvement of the instruments of your craft. Your skill as an operator has redounded to the credit of our school, not only at home, but everywhere abroad, and has not merely maintained, but immensely added to, the fame of our Alma Mater."

Sir Alexander Simpson made many contributions to medical literature. He edited Sir James Simpson's "Clinical Lectures on Diseases of Women," and was the author of "Contributions to Obstetrics and Gynæcology." "Axis-

[1] THE LANCET, August 25th, 1905, p. 410.

Traction Forceps," "Cæsarean Hystero-Oöphorectomy," "The Marriage Question from the Standpoint of Gynæcology," "Religio Obstetrici," and many obstetrical and gynæcological memoirs. He received the honour of knighthood in 1906, and was honorary or corresponding Fellow of many foreign societies. He was formerly honorary President of the Glasgow Gynæcological and Obstetrical Society, President of the Royal College of Physicians of Edinburgh, of the Edinburgh Obstetrical Society, and was Fellow of the Royal Society of Edinburgh. He also held the honorary degrees of D.Sc. Vict. and LL.D. Edin. He attended numerous international congresses as the representative of his University, where his unusually good linguistic powers served him well. In addition to his professional activities he was much interested in religious and philanthropic work, giving generously both in time and materially. He took an interest in Evangelistic work in Edinburgh, and especially in the mission movement among students. He married in 1872 Margaret Stewart, daughter of Mr. G. F. Barbour of Bonskeid. Lady Simpson died in 1912. He is survived by one daughter and four sons, one of whom, Dr. G. F. Simpson, is in the medical profession.

With Sir Alexander Simpson there passes from this world, full of years and honours, an earnest Christian, a benevolent and upright man, and one who worthily upheld the best traditions of the profession and the medical school to which he belonged.

We have received from Professor W. Russell, of Edinburgh, the following appreciation of his late colleague:—

"By the death of Sir Alexander Simpson Edinburgh has lost another of the most outstanding members of the medical profession and one of the best known of its citizens. The writer is old enough to remember Dr. Simpson's introduction to the chair vacated by the death of his uncle, Sir James Young Simpson. He remembers something of the feelings prevalent at that time, and, looking back over the years, he still recalls the calm courage, the steadfast eye, and the unshakable patience of the young professor. These qualities he showed right through life, down to the last day he moved amongst us. In the University it must have been the outcome of his faculty for affairs which led to his selection as Dean of the Faculty of Medicine, a post he held for a number of years. It was not, however, until he came to occupy the presidential chair at the Royal College of Physicians that his business capacity and marked fairness of mind became more widely recognised and acknowledged. The stable fairness of mind was combined in an unusual degree with a ready and spontaneous interest in and sympathy with the original work and observations of younger men. Never a fighting partisan his ready and generous recognition of merit and the facility in exactly expressing his understanding of the possible significance of work were sometimes misunderstood. It was not until men learned that he possessed a very wide knowledge of medical science, and was in close acquaintance with its most modern developments, that a truer estimate came to be formed of his character, of his judgment, and of his high mental capacity. Whatever slowness there was in some quarters to estimate him aright was in part at least due to the absence of forceful assertion, and the entire want of the spirit of egotism, of personal seeking of display which characterised him. His quick judgment and his gift of ready and fluent and appropriate expression without display came in due time to be fully understood and appreciated, so that as years passed he received the measure of high esteem and respect which a more assertive character might have commanded earlier. As showing the plasticity of a mind ever sensitive to real forward movement, the profession in Edinburgh was not a little amazed to find the heretofore obstetrician becoming, with the advance of abdominal surgery, a skilful and accomplished operating gynæcologist at an age when many surgeons are supposed to have passed their zenith. And when, having reached a certain age, he decided to lay down his University and hospital work the valedictory address he delivered on graduation day was unanimously recognised as one of the most striking addresses ever delivered on such an occasion. It was only occasionally that his wide erudition and clear and sympathetic thinking so displayed themselves so that all could realise that here was a type of man not of the ordinary medical market-place. When the question is asked what was at the back of all this, what was it that was making and moulding and permeating this man's life and character, the answer is certainly to be found in the extraordinary spirituality of his religious experience. And this side of Sir Alexander Simpson's life was necessarily much in evidence, for it brought him into active participation in all religious, both home and missionary, activities and all philanthropic movements."

Professor Russell concluded his sympathetic appreciation by quoting some passages in which the Rev. Dr. Kelman[2] bore striking testimony to Simpson's spirituality. Reluctantly space compels us to omit all but these eloquent words:—"His home was proverbial for its hospitality. Strangers came to it from many lands, until it seemed to be a home for all the world. ..... His life-long delight in young men kept for him the secret of perpetual youth. ..... They went to him in joy and trouble, in temptation and in shame. Struggling men, broken men, despised men, went and never found him weary or preoccupied. No dullness bored him, no failure estranged him or alienated his compassion or checked his generosity."

ARTHUR EDWARD JAMES BARKER, F.R.C.S. ENG., F.R.C.S. IREL., &C.,

LIEUTENANT-COLONEL, R.A.M.C.; CONSULTING SURGEON TO THE SOUTHERN COMMAND; PROFESSOR OF SURGERY AND CLINICAL SURGERY, UNIVERSITY COLLEGE HOSPITAL.

As we briefly announced last week, Colonel Arthur Edward James Barker died on active service on April 8th, after an attack of acute pneumonia and nephritis.

Mr. Arthur Barker, who was in his sixty-sixth year, was born in Dublin, and was the son of Dr. William Barker of that city. He received his medical education at the school of the Royal College of Surgeons in Ireland and afterwards studied at Bonn University. In 1870 he became a Licentiate of the Royal College of Surgeons in Ireland and five years later a Licentiate of the Royal College of Physicians of Ireland. He took the Fellowship of the Irish Royal College of Surgeons in 1876 and received the English diploma *ad eundem* in 1880. For a time Mr. Barker acted as surgeon at the City of Dublin Hospital, but in 1875, when only 25 years of age, he joined the staff of University College Hospital, London, becoming surgeon in 1885. In 1893 he was appointed Professor of the Principles and Practice of Surgery and of Clinical Surgery at the Medical School attached to the College. He was a consulting surgeon to the Queen Alexandra Military Hospital, Millbank, and to the Osborne Convalescent Home for Officers, and shortly after the outbreak of the war was appointed temporary lieutenant-colonel in the R.A.M.C., serving as consulting surgeon to the Southern Command. He was examiner in surgery to the University of London, and among other appointments which he had held were those of examiner in surgery to the Victoria University, and Hunterian professor in surgery and pathology at the Royal College of Surgeons of England. When the British Medical Association held its seventy-seventh annual meeting at Belfast in 1909 Mr. Barker delivered the address in Surgery—an address marked by optimistic thought and foresight as to the future position of surgery.

His contributions to surgery were numerous and important. In an early investigation into the results of leukoplakia of the tongue he was able to show that in a large proportion of the cases epithelioma of the tongue ultimately developed, and these conclusions were of good effect in drawing attention to the need for early treatment of this condition. When abdominal surgery began to develop, Mr. Barker was one of the pioneers in this country, and the work which he wrote on abdominal operations appeared at a time when little had been written on the subject in the British Isles; and in this connexion we may mention that the first successful gastro-enterostomy for malignant disease of the pylorus in this country was performed by him. This was only the first of a very long series of similar operations successfully performed. In the surgery of the brain he was also much interested, and one case upon which he operated deserves special mention. In this case he removed a bullet from the upper surface of the corpus callosum with complete success, the patient recovering without a symptom from what promised to be a fatal injury. He early devoted attention to spinal anæsthesia, and employed the method very widely; he always administered the anæsthetic himself, and it was very

[2] On the occasion of the memorial and thanksgiving service held in St. George's U.F. Church, Edinburgh, on April 12th.

rare indeed for the anæsthesia to prove in the least unsatisfactory. He was, we believe, the first to use glucose in the injection fluid for spinal anæsthesia, and with this method of anæsthesia he was completely satisfied. Mr. Barker was extremely ingenious and he invented several useful surgical instruments, among which may be specially mentioned the "surgical sewing machine," a device for allowing the surgeon to use a thread of practically unlimited length, without having the need to re-thread the needle; it was mainly intended for use in abdominal surgery, but it could be employed in any region of the body. He was a skilful mechanician, and he always made a model of his inventions himself, and thus they were carefully adjusted for the purpose for which they were intended. He was very careful in the planning and in the carrying out of all operations; he operated deliberately, neatly, and with the most careful attention to details, and it may be mentioned that he preferred linen thread to silk for sutures and ligatures. A short "Manual of Surgical Operations," which he published in 1887, was a valuable acquisition to the records of operative surgery, well written and illustrated in a manner which testified to the author's skill as a draughtsman. He also contributed to Holmes's and Treves's Systems of Surgery and Burghard's System of Operative Surgery, and was the author of numerous papers on surgical subjects to the medical journals.

Dr. Herbert Spencer writes: "I knew Arthur Barker for over 35 years as teacher, colleague, and friend, with increasing admiration as the years went by. During such a long period of friendship the little personal peculiarities of our friends, from which few are free, become neglected; we pay more regard to the sterling value when the surface markings are obliterated, and we are able to appreciate that 'a man's a man for a' that.' Such a man, and a good man, was Arthur Barker. He came to University College Hospital from Ireland at an age when no one can have an extensive or deep knowledge of any branch of medicine. His great merit lies in the fact that he devoted himself with the utmost energy and assiduity to increasing his knowledge until he became one of the most learned and skilful surgeons in this country. During the period of 40 years' work as surgeon to University College Hospital he set an admirable example in the performance of duty, doing an enormous amount of work both by day and night up till the age of 65, when he retired from the active staff. Only one endowed with his magnificent physique could have done this work without exhaustion. I never remember to have seen him tired.

As a teacher he perhaps sometimes spoke a little over the heads of the ordinary student and was apt to dwell on grand, extraordinary, and rare cases. It was the best students and those reading for the higher degrees who appreciated him most. He was rather a teacher of teachers than of students. No one known to me had such a comprehensive knowledge of the literature of new processes and observations in surgery—a fact to be attributed to his excellent knowledge of German and French and to his frequent, at one time yearly, visits to the Congress of German Surgeons. He was thus frequently a year ahead of stay-at-home surgeons in his knowledge of new methods of treatment. If these commended themselves to his judgment he would make trial of them and bring the subject before the profession in a well-written paper which often led to its wide adoption. To him more than to any surgeon in this country is due the use of aseptic dressings and methods and of spinal anæsthesia. He was supremely skilful as an abdominal surgeon—cool, bold, quick, resourceful, with the deftest hands. It was an education to see him suture intestine.

In the charming circle of his family and in familiar conversation over a cigar Barker was at his best. He had then a power of clear and apposite expression, not always evident when he spoke in public, with occasional brilliant flashes of wit, which delighted his friends. I never heard him speak ill of anyone. I have seen a charming letter to a friend written by him on April 1st from a tent on the foothills around Saloniks, in which he said he was well and spoke hopefully of the future. A few days later he was dead. His death came as a grievous surprise to those who knew his splendid constitution and who hoped he had many years of activity in front of him and that his work would receive some recognition from the State. Barker came of a family of soldiers, and it was a fitting and noble ending to a well-spent life for him to die in the service of his country. His work, his school, his pupils, and his friends will keep his memory green."

THE LATE SIR THOMAS BOOR CROSBY.

Dr. R. Hingston Fox writes: "May I supplement your valuable account of Sir Thomas Crosby by a few further notes? He was one of the old habitués of the Hunterian Society, being the senior Fellow on its list at the time of his death, and having acted as Orator in 1871 and President seven years later. His presence at the meetings always brought with it a breath of genial life; his comments were terse and vigorous—he would refer to the 'honourable member' who had just spoken; and whether in these discussions or at the annual dinners, he contributed not a little to the social, friendly, and frank tone for which the gatherings of that society used to be noted, in the days when a city medical community existed. When he began to practise in Fenchurch-street there were still good residences, so he has told me, there and in the neighbouring streets, some with gardens and fountains in them. His friends will remember him especially for his extraordinary fund of vital energy, which has carried him, still in harness, to so advanced an age. To a doctor such a spring of life was a priceless gift, for every patient felt its magnetic force, and many a one was lifted by Crosby's sane and breezy manner out of his despondent mood. The twinkle of humour seldom left his eye; he was in the world to heal, to better, and to extend good fellowship."

At the last meeting of the Court of Common Council of the City Corporation Mr. Mann Cross moved a resolution of condolence with the family of the late Alderman Sir Thomas Boor Crosby, who for nearly 39 years had rendered valuable services to the citizens. Mr. Mann Cross described the deceased alderman as keen, alert, and vigorous both in mind and body, of a bright and optimistic disposition, and respected and beloved by a very large circle of friends. Sir Alfred Newton, as the senior Alderman present, seconded the resolution. He said that in Sir Thomas Crosby they had lost an able and effective magistrate, a man who gave utterance in no unmistakable terms to his convictions, who ever tempered justice with mercy, and whose memory was held in deep reverence by all who knew him. The resolution was carried in silence.

THE LATE DR. J. K. SPENDER.—John Kent Spender, M.D. Lond., M.R.C.S. Eng., L.S.A., who retired in 1895, died at his residence in Bath on April 14th at the age of 87. He was the son of the late Mr. John Cottle Spender, M.R.C.S., of Bath. Dr. J. K. Spender had been surgeon to the Western Dispensary, Bath, from 1855 to 1872 (where he had a large experience in the treatment of syphilis and strongly advocated mercurial treatment) and physician to the Royal Mineral Water Hospital, Bath. He was the author of papers on syphilis in THE LANCET of 1869 and 1874, and of "Therapeutic Means for the Relief of Pain," which was awarded the Fothergill gold medal of the Medical Society of London in 1874. He also wrote "The Bath Thermal Waters, Historical, Social, and Medical," in 1877, and on Rheumatoid Arthritis in 1889. His wife, who died many years ago, was well known as a writer, and one of his sons is Mr. J. A. Spender, the editor of the *Westminster Gazette*.

BEQUESTS TO BRIGHTON CHARITIES.—By the will of the late Miss Elizabeth Simpkins, of Brighton, the testatrix left £5000 to the Sussex County Hospital; £1000 each to the Royal Alexandra Hospital for Children, the Brighton and Hove Branch of the Surgical Aid Society, the Throat and Ear Hospital, the Eye Hospital, the Asylum for the Blind, and the Asylum for Deaf and Dumb Children; and £500 to the Crèche in Eastern-road.

THE ROYAL SANITARY INSTITUTE.—A conference on Sanitary Administration under War Conditions will be held in London on June 9th and 10th. On June 9th, at 10.30, the conference will be opened by the Lord Mayor of London. A discussion on "The Maintenance of the Standard of Municipal Sanitation during the Continuance of War Conditions" will be opened by Mr. H. Percy Boulnois, M.Inst C.E., and Dr. James Wheatley (Shrewsbury). The chair will be taken by the Mayor of Westminster. On June 10th a discussion will be opened on "The Mental Deficiency Act from the Social and Educational Standpoint" by Dr. A. B. Ritchie (Manchester). The chair will be taken by Mr. Leslie Scott, K.C., M.P. At 3 P.M. each day visits will be made to various undertakings. A lecture to the Institute on "The Economics of Food-supply in War Time," by Dr. Augustus Waller, F.R.S., will be given on May 3rd at 5.30 P.M. Lieutenant-Colonel Sir Shirley Murphy, F.R.C.S., R.A.M.C., will occupy the chair.

Correspondence.

"Audi alteram partem."

THE STUDY OF APPLIED PSYCHOLOGY.

To the Editor of THE LANCET.

SIR,—During the last few months several papers on the psychology of shell shock and cognate conditions have been published in your columns. One striking feature is the attraction which such problems have for a wider intellectual circle than the professed psychologist or psychiatrist, a fact which is well exemplified by the case of the distinguished anatomist, Professor Elliot Smith, whose contribution to THE LANCET emphasises not only the interest but the profound importance, both social and individual, of the topic which he deals with. Your leading article of April 15th contrasts the admirable paper of Dr. Bernard Hart on the psychology of rumour with the spiritualistic fantasies of M. Maeterlinck, which are rightly censured, though with regret at the degradation of a great poetic genius. Two books, one by Sir Martin Conway, the other by a well-known surgeon, Mr. Wilfred Trotter, have recently been published on the psychology of the crowd.

The newspapers teem with material of surpassing interest to the psychologist. There we see the peace-bred politician, accustomed to be passively impelled along his victorious path by the united opinions of a great party, now confronted with the mandate to lead, a rôle which his education and experience render him singularly unfitted to fill. We see the permanent official, inured to routine and a wholesome dread of responsibility, suddenly called upon to reorganise his department on new lines and to expand it to meet the urgent requirements of a critical situation, a task which he has never contemplated and is usually little adapted to. We see the multitudinous critics, accustomed to the apparent freedom of individual thought which is the offspring of a democratic environment, voicing their panaceas in the press with little result but to make confusion worse confounded. Even our scientific experts, Fellows of the Royal Society though they may be, are so narrowed by the cramping influences of lives passed in the laboratory and class-room that they show a lamentable inability to realise the broader aspects of the struggle, and, above all, fail to do justice to the practical problems which it has been their habit to view with Olympian indifference. Every one babbles of causes and effects with a logical accuracy which is only stultified by false premises. In spite of the proved failure of the theorists of the French Revolution and after —Rousseau, the Utilitarians, and *hoc genus omne*—and because of the growth and predominance of rationalism and its many favourable and advantageous results, we are more than ever convinced that man differs from the lower animals in being endowed with reasoning faculties and works out his salvation by them.

Yet we are equally convinced that not only our bodies but our minds have evolved from those of lower species, and that even the individual in some modified manner recapitulates his phylogenetic history in his own development. Comparative psychologists like Professor Lloyd Morgan have done much to elucidate the mentality of lower animals and the parts played by instinct and intelligence. Genetic psychologists like Professor Mark Baldwin, whose escape from a dastardly death at the hands of the Germans we all rejoice in, show how great a part instinct, modified indeed but clearly recognisable, plays in the mentality of the child. Social psychologists like Professor William McDougall further demonstrate how instinct permeates and pervades life from the cradle to the grave. Anthropological psychologists like Durkheim and his school, and especially Lévy-Bruhl, emphasise the corporate mentality of primitive races, its emotional responses, its "prelogical" indifference to incompatibles, and, above all, its predominant group-unity. The evolution of the individual mind and its gradually increasing segregation from the communal mind has yet to be traced down the course of the ages. When that is done we shall have attained a scientific psychology of history which will replace the speculative philosophies of history, which are the natural outcome of transcendental philosophy. Thus shall we lead up by slow but sure progress to a really scientific comprehension of the motives, and therefore of the actions of individuals in their social relations. Psychology, after centuries of sterile individualistic introspection, has at last become a practical science, with all knowledge for its realm. Sooner or later its teachings must be recognised as the only sure foundation for education in all its branches. By it alone can any truly scientific guidance be given to democratic thought and action.

This long preamble is a brief and inadequate review of some of the reasons why I think the time is ripe for the formation of a society to deal with the innumerable problems of what may be called applied psychology. Why do I ask you, Sir, to ventilate this suggestion? First, because I think that scientific psychology must be founded on physiology, and that those who have been well trained in physiology and neurology must be the guiding spirits of any such enterprise. Second, because morbid psychology has advanced farther along the practical lines of an applied psychology than any other branch of the subject. Third, because the problems of this nature which the war has so strikingly brought to light have revealed the widespread interest in the subject as well as, to many people, the inadequacy of the methods available for dealing with them. Fourth, because I think this is the best way to obviate the greatest danger which such a society would be confronted with—viz., over-popularity. It would be fatally easy for it to degenerate into a medium for pseudoscientists, faddists, and fanatics. Already scientific eugenics has had reason to pray to be saved from some of its friends. To avoid such a disaster I think (1) that the society must be run on oligarchical lines—the council must have complete control; and (2) that at least half of the council must consist of professional psychologists and psychiatrists of established reputation, the remainder representing other interests. It would be easy to enumerate specially qualified anthropologists, classical scholars, historians, and so on. To avoid the dangers of too autocratic a government I would advocate a large committee on the above lines, with a small executive subcommittee. Such a society holds out an alluring prospect of useful work in many spheres of public endeavour. The argument that the present time is little suited for embarking upon a project of this nature is worthy of deferential consideration, but I would submit that there are obvious reasons why it would be wise to coördinate the discussions of the many problems which the war has exhibited in an acute form. The universal cry of the moment is for organisation of effort. Doubtless we shall muddle through now as of yore, but we are no longer content to muddle on indefinitely. Now is the time to lay the foundations of future organisation, and I would point out that the organisation of a democracy like ours is a far slower, subtler, and more complicated task than the organisation of a pack of wolves (like the Germans) or a flock of sheep.—I am, Sir, yours faithfully,

J. HERBERT PARSONS.

Queen Anne-street, W., April 15th, 1916.

INFLUENCE OF FEBRILE CONDITIONS ON INOCULATION AGGLUTININS.

To the Editor of THE LANCET.

SIR,—In recent articles Professor G. Dreyer and his co-workers have commented adversely on certain methods in common use for measuring agglutination and also on certain results obtained in persons inoculated with B. typhosus. I should like to refer to three of these questions —(1) the value of the microscopic method; (2) the effect of febrile conditions on inoculation agglutinins; and (3) the comparative value of a positive reaction to B. typhosus in inoculated and non-inoculated persons.

1. The value of the microscopic method. Dr. E. W. Ainley Walker in THE LANCET of Jan. 1st argues that this method is unreliable. None of his reasons applies specially to the microscopic method, and every argument he advances applies equally to the macroscopic or any other method which involves the use of living cultures. Bacteriologists are quite aware of these difficulties, and have to be constantly on the look out to avoid them, and whatever their importance in theory, in practice undoubtedly they are avoided. These methods, microscopic, macroscopic, and mixed, have been in use for many years, and their results are confirmed by the diagnosis of clinicians and by post-mortem examination. If Dr. Walker wishes us to believe

that these results have been grossly fallacious, as he apparently does, he will find little evidence to support him and few to follow him. Without doubt the difficulties with typhoid cultures do exist, although they can be avoided, and if Professor Dreyer can give us a standard culture it will be a great boon. Unfortunately, Professor Dreyer and his colleagues have thrown together two entirely independent questions, the advocacy of the use of killed cultures and the advocacy of a certain technique. The killed typhoid suspension sent to me could not have contained more than 200–300 million bacilli per c.c., and was thus too thin for use except presumably by his own technique. If Professor Dreyer would provide killed suspensions containing 1500–2000 million per c.c., I am sure he would find their use would receive a full and sympathetic trial.

2. The effect of febrile conditions on inoculation agglutinins. Some time ago the writer made the suggestion that agglutinins resulting from typhoid inoculation are markedly diminished or removed by febrile conditions, in which a temperature of 102° F. is present for at least four days. Professor Dreyer, Dr. A. G. Gibson, and Dr. Walker very emphatically deny this in THE LANCET of April 8th, and in support of their views give tables of the results obtained in series of cases of paratyphoid A, paratyphoid B, and "other febrile conditions." In order to ascertain whether these series show any diminution of agglutinins as the result of the febrile attack, the number of Dreyer's "standard agglutination units" present must be compared with the number found by the same method in healthy inoculated persons. The latter figures are given by Professor Dreyer and Dr. A. C. Inman in THE LANCET of July 31st, 1915. The mean number of typhoid agglutination units present in each case in the various series is as follows:—

Normal typhoid inoculated persons	225 typhoid agglutination units.
Paratyphoid A occurring in typhoid inoculated persons ...	37 typhoid agglutination units.
Paratyphoid B occurring in typhoid inoculated persons ..	150 typhoid agglutination units.
Other febrile conditions occurring in typhoid inoculated persons	78 typhoid agglutination units.

A standard of comparison suggested by Professor Dreyer, Dr. Gibson, and Dr. Walker is the percentage of cases in each series in which at least 25 typhoid agglutination units are present. In comparison with the normal inoculated persons, the results are:—

Normal typhoid inoculated persons	100 per cent contain 25 units.
Paratyphoid A occurring in typhoid inoculated persons ...	57·1 per cent. contain 25 units.
Paratyphoid B occurring in typhoid inoculated persons ...	81·9 per cent. contain 25 units.
Other febrile conditions occurring in typhoid inoculated persons	54·5 per cent. contain 25 units.

The tables may be compared in various ways with the same result. There is always a marked diminution of agglutination in patients who have passed through a febrile attack. Some other tables previously published by Professor Dreyer and Dr. J. A. Torrens are also reproduced in this article. There is no statement either of the number of units or whether the agglutination referred to is "standard agglutination" and therefore it is not possible to compare them with other tables, but it is evident that the febrile cases have distinctly less agglutinin than the normal inoculated persons. Thus a consideration of the results published by Professor Dreyer and his colleagues strongly supports the suggestion that the passage through a febrile attack markedly diminishes the amount of typhoid inoculation agglutinins.

3. The comparative value of a positive typhoid agglutination reaction in inoculated and non-inoculated persons. The suggestion made by the writer was that a febrile attack of 102° F. for at least four days so far reduces the inoculation agglutinins that if subsequently the typhoid agglutinins reach the standard which would be regarded as positive in a non-inoculated person, the reaction should be regarded as positive even in an inoculated person. It is obvious that if such an attack does produce this reduction, the second hypothesis is almost a necessary sequel, and it has been shown that the figures published by Dreyer strongly support the primary suggestion. Of 102 cases of paratyphoid, &c., in Dreyer's tables which had passed through febrile attacks, only 13 showed more than 100 "agglutination units." It is not unreasonable to ascribe 8 of these to co-agglutinins. Thus there remains 5 per cent. of cases after febrile attacks in which the presence of 100 units may be due to inoculation. (It may be mentioned that this amount is present in 58 per cent. of normal inoculated persons in Professor Dreyer and Dr. Inman's tables.) This number of 100 units apparently corresponds to a "positive" reaction in non-inoculated persons. It is evident that there is nothing in these figures to controvert the view that after an inoculated person has passed through a febrile attack the value of a positive typhoid reaction is but little less than in a non-inoculated person.

The primary suggestion on which this view was based is that a febrile attack of 102° F. for at least four days markedly diminishes the inoculation agglutinins, and this conclusion is strongly supported by all the results recorded by Professor Dreyer and his colleagues, although their figures were published expressly to refute the suggestion.

I am, Sir, yours faithfully,

Greywell, Bursledon, Hants, April 13th, 1916. H. L. TIDY.

TREATMENT OF HÆMORRHOIDS BY INJECTION.

To the Editor of THE LANCET.

SIR,—Whilst feeling greatly flattered by Mr. Swinford Edwards's kindly reference to myself in his article on this subject in THE LANCET of April 15th, I cannot agree with him in his reasons for objecting to the use of the speculum for the little operation, nor with his choice of cases for the method. I make it an invariable rule in every rectal case to use the speculum, because it is only in this way that most rectal lesions can be accurately diagnosed. There are numerous cases of hæmorrhoids in which bleeding, pruritus, or other troublesome symptoms exist, but in which the piles rarely or never prolapse and cannot be made to do so. Hæmorrhoids cannot be felt even by the most highly trained finger. There is only one way to diagnose them, and that is by seeing them. If they are large and prolapse readily this is easy; but in the majority of cases the only way of seeing them is to pass a speculum. Nearly every patient with a rectal lesion diagnoses it himself as "piles," but nobody knows better than Mr. Edwards in what a large proportion of cases that diagnosis is incorrect or incomplete. Naturally before treatment is started a complete diagnosis is necessary, and thus the possession of a rectal speculum is a *sine qua non* to anyone treating a rectal case. Since Mr. Edwards only injects piles that can be protruded either naturally or after an enema, and condemns all other cases to a continual use of "local applications, enemata, attention to diet, and regulation of the bowels, &c.," he deprives by far the larger class of patients of the benefits of the injection method, and reserves it for the worst cases, in which its success is least certain. Moreover, the use of an enema is a very awkward complication in private practice, and practically prevents the use of the method at the surgeon's consulting-room, whilst it would be a very troublesome addition to the treatment at an outpatient department, where numerous cases have to be dealt with in a limited time,—I often inject a dozen or more cases in an afternoon. Contrary to Mr. Edwards's expectation, I never need an assistant, though I always use a speculum; were I to use an enema, however, the assistance of a nurse, both at hospital and in private, would seem to be essential. Nor have I had any trouble from hæmorrhage, which never exceeds a few drops that can be readily soaked up with a single swab. Mr. Edwards seems to get much more bleeding by injecting piles outside the anus, and this is a serious drawback to his method. I find it quite easy to inject the fluid into the centre of each pile, or into its base, and I can easily reach high-lying piles by means of the speculum—piles which, though large, are unlikely to come down outside the anus.

I think it necessary to emphasise these points, because Mr. Edwards would restrict the cases he thinks suited to injection to the more severe ones, and it is especially in the milder ones, which he condemns to palliative treatment, that I have found injection most useful. Our difference in technique accounts, I think, for our difference in practice.

I am, Sir, yours faithfully,

Gordon-square, W.C., April 17th, 1916. ARTHUR S. MORLEY.

TREATMENT OF HÆMORRHOIDS.

To the Editor of THE LANCET.

SIR,—I have read with much interest Mr. Swinford Edwards's paper in THE LANCET last week on the treatment of piles by injection. When I was house surgeon at St. Mark's Hospital I had the privilege of seeing him carry out this plan, and my opinion is favourable to the procedure. I agree with him that experience tells. Many a good treatment receives adverse comment, and patients suffer needless pain, at the hands of those who will not learn correct practical details to assist them in diagnosis or technique.

I am, Sir, yours faithfully,

Bournemouth, April 17th, 1916. W. J. MIDELTON.

ENTERIC AND TYPHOID: A POINT IN NOMENCLATURE.

To the Editor of THE LANCET.

SIR,—In reference to Dr. E. W. Goodall's letter on this subject in your issue of April 15th, may I mention that the arrangement which he suggests had already been adopted by the Committee of the Nomenclature and Classification of Diseases, Royal College of Physicians? The entry of enteric fever in the section "Diseases caused by Infection," as revised by the committee, now stands as follows:—"Enteric fever:—Varieties: (*a*) Typhoid fever, (*b*) paratyphoid fever." The organisms concerned in the causation of the different varieties of enteric fever will be found in the list of vegetable parasites.

It is hoped that the 1916 edition of the Nomenclature and Classification of Diseases will shortly be in the press.

I am, Sir, yours faithfully,

LEONARD GUTHRIE,
Honorary Secretary, Nomenclature of Diseases Committee, Royal College of Physicians of London.

Upper Berkeley-street, W., April 17th, 1916.

UREASE.

To the Editor of THE LANCET.

SIR,—In the account of the meeting of the Royal Academy of Medicine in Ireland given in THE LANCET of April 8th (p. 781), Dr. W. G. Smith is reported to have said that in the estimation of urea the most accurate method is by urease. Will any of your readers kindly inform me what is the technique and where urease can be obtained?—I am, Sir, yours faithfully,

Belfast, April 11th, 1916. RICHARD PURDON.

*** Our correspondent will find a clear account of the technique in Mr. R. H. A. Plimmer's "Practical Organic Chemistry" (Longmans, Green, and Co., 1915 edition). The enzyme urease need not be used separated from the soya bean. A little pinch of the soya bean powder suffices, and the soya bean is not difficult to procure.—ED. L.

ANÆSTHESIA FOR ENUCLEATION OF TONSILS.

To the Editor of THE LANCET.

SIR,—Dr. Hugh R. Phillips, in your issue of April 15th, rather misses the point of my article when he sums it up in the statement that I "advocate the use of ether" for enucleation of tonsils. I advocate the use of some ether during the induction. What I was seeking to enforce is that (1) a very deep degree of narcosis is necessary; (2) some ether is desirable in attaining this; (3) anæsthesia in these cases requires skill and experience to produce; and (4) the anæsthesia is maintained by chloroform.

I am, Sir, yours faithfully,

Harley-street, W., April 15th, 1916. J. BLOMFIELD.

NATIONAL ASSOCIATION FOR THE PREVENTION OF INFANT MORTALITY.—A special course of lectures on Infant Care for Nurses and Midwives will be held from May 8th to June 23rd, from 3 to 4 P.M., on Mondays, at 1, Wimpole-street, London, W., and on Fridays, at 3, Vere-street, W. Particulars may be obtained from the Secretary, 4, Tavistock-square, London, W.C. Medical practitioners and students may attend.

The War.

THE CASUALTY LIST.

THE following names of medical officers appear among the casualties announced since our last issue:—

Died of Wounds.

Lieutenant M. E. Ball, R.A.M.C., attached to the Worcestershire Regiment, was a student at Guy's Hospital, qualifying in 1909, and was in practice at Emsworth, Hants, before joining the R.A.M.C. in September, 1915.

Wounded.

Lieutenant J. Coutts, R.A.M.C.

Lieutenant J. M. MacKenzie, R.A.M.C., attached to the Northumberland Fusiliers.

Lieutenant M. G. Pettigrew, R.A.M.C., attached to the Welsh Regiment.

Lieutenant R. R. Pirrie, R.A.M.C., attached to the Northumberland Fusiliers.

Captain H. W. Greig, R.A.M.C.

Lieutenant M. G. MacDonald, R.A.M.C., attached to the Royal Warwick Regiment.

Captain J. McKerchar, R.A.M.C., attached to the Somerset Light Infantry.

DEATHS AMONG THE SONS OF MEDICAL MEN.

The following sons of medical men must be added to our lists of those who have fallen during the war:—

Captain S. Powell, Royal Welsh Fusiliers, youngest son of Sir R. Douglas Powell, Bart., K.C.V.O., M.D.

Lieutenant W. M. Dobie, Royal West Kent Regiment, son of Dr. H. Dobie, of Chester.

Captain H. B. Dobson, Worcestershire Regiment, third son of Mr. N. C. Dobson, F.R.C.S., of Clifton, Bristol.

Sergeant H. W. Welstead, Canadian Expeditionary Force, third son of Dr. F. Welstead, of West Dulwich, Surrey.

Captain G. Y. Gross, Royal West Kent Regiment, second son of the late Mr. C. Gross, F.R.C.S., of Westbourne-grove, London.

THE HONOURS LIST.

For distinguished service and devotion to duty at the camp at Wittenberg, Germany, during the typhus epidemic from February to June, 1915, the following honours have been conferred:—

To be C.M.G.: Major H. E. Priestley, R.A.M.C.

D.S.O.: Captain A. C. Vidal, R.A.M.C., and Temporary Captain J. La F. Lauder, R.A.M.C.

The following promotions and appointments of medical men in connexion with Indian Army Services are announced:—

To be C.B., Military Division.—Colonel H. M. Adamson; Lieutenant-Colonel J. F. Donegan, R.A.M.C.

To be Brevet-Colonel.—Lieutenant-Colonel E. Jennings, I.M.S.

To be Brevet-Lieutenant-Colonel.—Major S. Anderson, I.M.S.

Distinguished Service Order.—Captain P. B. Bharucha, I.M.S.

Military Cross.—Captain R. C. Clifford, I.M.S.; Captain F. A. Robinson, R.A.M.C.; Lieutenant F. T. Simpson, R.A.M.C.

COMPULSORY MILITARY SERVICE.

It is possible that before the publication of THE LANCET this week the country will know the decision that has been come to in Parliament on the question of compulsory military service. In respect of the various political considerations that have obscured the question a medical journal has nothing to say; they have had their origin to some extent in the progress of the war, and only a foresight that would have amounted to prophesy could have obviated the difficulties that have arisen. As far as the medical profession is concerned, it seems almost beyond doubt that a general demand upon the medical profession at the beginning of the war would have yielded a more equitable result than that which has now been

obtained through the self-sacrifice and patriotism of large numbers of individual practitioners. If the whole material had been available from the beginning, levies could have been made from it that would have been more fair to the constituency as a whole, while the risk of the dangerous depletion of civil practitioners in particular localities would have been avoided. The men most suited for the work and most easily spared from their civil duties could in this way have been employed, and to some extent employed in places congenial to their capacities. We do not deduce from this that compulsory military service for the population is now necessary—all arguments from the particular to the general are dangerous—but it seems to us a fact that a measure of compulsion earlier in the war would have had the same good outcome for the whole population of the country that it would have had for the medical profession.

THE HORRORS OF WITTENBERG CAMP.

Sir WILLIAM MILLIGAN writes as follows concerning Wittenberg Camp:—

The horrible and ghastly tale of the inhuman conduct of Dr. Aschenbach, the medical officer in charge of the Wittenberg prisoners of war camp, as reported by the Government Committee on the Treatment by the Enemy of British Prisoners of War, is only one more illustration of the infamous effects of German Kultur (!). I doubt if the medical profession of any country in the world could produce such a specimen of depravity as this inhuman beast, the medical commandant to whom the Kaiser has presented the Iron Cross as a reward for the perpetration of systematised murder on a colossal scale.

It is time, Sir, that the medical profession in this country raised its voice in abhorrence and in condemnation of the conduct of a confrère who, trusted with the care of suffering and defenceless prisoners of war, so betrays his trust as to be capable of such cowardly and devilish barbarity as this traitor to our profession.

"Man's inhumanity to man
Makes countless thousands mourn."

To mark the feelings of indignation and disgust shared by the medical profession of the British Empire I beg to suggest that the Councils of the various Sections of the Royal Society of Medicine forthwith delete from their list of Honorary or Corresponding Members the name of any German physician, surgeon, or specialist, who may have in our hour of illusion and delusion been accorded this honour.

I may say that I have given notice of a resolution on these lines to the secretary of the Laryngological Section and of the Otological Section of the Royal Society of Medicine for discussion at the first possible opportunity.

EMERGENCY MILITARY HOSPITALS.

At the Royal Sanitary Institute last week, Mr. A. Saxon Snell, F.R.I.B.A., repeated, with new points and illustrations as a Chadwick lecture, an address on the same lines as one delivered before the Royal Society of Medicine on Nov. 10th, 1915 (THE LANCET, vol. ii., 1915, p. 1164). He showed that the many lessons to be afforded by the construction of temporary military hospitals, and the conversion of private houses into places suitable for the care of the sick and wounded during the war will inevitably affect the design and cost of hospitals, both temporary and permanent, when we return to normal times, and Mr. Snell's summary of what has been already done to meet present conditions will prove highly valuable in the future. The important factors in good hospital construction are sunlight, fresh air, and cleanliness, and these factors, he pointed out, were particularly necessary in temporary structures, as they compensated for the lack of finish to the floors and surfaces of the buildings, permitting of the accumulation of dust and perhaps promoting germ growth. Fresh air he estimated as more important than heat, and its beneficial effects were well observed in the Crimean War, where the mortality among the wounded treated in places exposed to the open air was considerably lower than that among those treated in closed buildings. Similar lessons, Mr. Snell said, were gained by surgeons in the American War and in the Franco-Prussian War. Open-air treatment he admitted to have one serious disadvantage: the staff may be unfavourably affected thereby, or at any rate rendered very uncomfortable. But the experiences of Dr. Philip Boobbyer, medical officer of health of Nottingham, have shown that nurses can be trained to work in the open-air ward, and in the end may come to prefer that kind of ward to any other. In an open ward fires, he said, were necessary, even though they were not numerous and had no effect in heating the building; while they gave an appearance of comfort they were necessary so that nurses should have some means of warming their hands before applying dressings, and some handy place for raising the temperature of any small article of food. It was quite possible, in Mr. Snell's opinion, to build comfortable and efficient buildings at a small cost, but in wards for the reception of fever patients and infectious cases, even in temporary buildings, it was necessary to use those devices which were designed to promote cleanliness and prevent germ growth such as rounded angles and glazed walls. The same thing applied to operating theatres. It might be argued that if a hospital such as the 1st Eastern General Hospital at Cambridge could be built for £20 per bed it would be reckless extravagance to pay £150 per bed; but such a question would not be raised by those who understood hospital needs in times of peace. Discussing the question of what was necessary in the construction of permanent hospitals in the future, the lecturer said that one of the first things to be done would be a modification of the building by-laws. Hospital fittings that were not absolutely necessary would have to be rejected. Cement could be used in place of tiles, but little saving could be effected in metal fittings, as they were the most durable and economical. Heating apparatus might be dispensed with, but means must be provided for efficient ventilation. The lecture was illustrated by an interesting series of plans and views of military hospitals throughout the country. In one case the serious defect of not providing escape in case of fire was pointed out, and in another a proposal that there should be five rows of beds in a ward was severely criticised. A view of the Moabite Hospital in Berlin, which was erected as a temporary hospital some 40 years ago, and which is still standing, was thrown upon the screen.

THE BATH WAR HOSPITAL.—The Bath War Hospital was opened for inspection recently. It is situated in Coombe Park, Weston, and will provide accommodation for 500 wounded soldiers. The hospital has been erected by the War Office, but about £10,000 is being raised in Bath for the provision of accessories, and when patients arrive comforts will be provided for them by voluntary organisation. Dr. G. A. Bannatyne, of Bath, who holds the temporary rank of Lieutenant-Colonel, is the Commandant, and each of the ten wards will have a local surgeon.

THE Order of the White Eagle has been conferred upon Dr. Elsie Inglis, Commissioner of the Scottish Women's Hospitals for Foreign Service, by the Crown Prince of Serbia.

Medical News.

ROYAL COLLEGES OF PHYSICIANS OF LONDON AND SURGEONS OF ENGLAND.—At the quarterly examination in Practical Pharmacy held on April 6th and 7th the following candidates were approved:—

Abdul Majid Ahmad, Cambridge University and Guy's Hospital; Fritz Ernest Bendix, Middlesex Hospital; Ingram Richard Rhodes Brogden, Cambridge University and Guy's Hospital; Gordon Ernest Burton, Cambridge University and St. Bartholomew's Hospital; Henry Alexis Chodak, St. Andrews University and London Hospital; Alfred Beresford Dummere, London Hospital; John Reginald Keith Fenning, London Hospital and private study; Gerald Hartas FitzGerald, Guy's Hospital; Frederick Christopher Ashley Frith, Bristol University; Theodore Hamnet Gunewardene, Ceylon Medical College and King's College Hospital; Newcome Herbert Harrison, Charina Cross Hospital; Sidney Gilbert Harrison, St. Bartholomew's Hospital; Walter Sebastian Herman, London Hospital; Douglas Leonard Lees, Bristol University; Herman Siegfried Nicolaas Menko, London Hospital; Frederick Maurice Moseley, Cambridge University and London Hospital; William Percival Nelson, Birmingham University; Arthur Leslie Packham, Middlesex Hospital; David Forsyth Panton, London Hospital; Warre Harriott Alexander Pratt, Guy's Hospital; John Sturges Ranson, Westminster Hospital; Cecil Nuttall Ratcliffe, Liverpool University; Johannes Jacobus Redelinghuys, University College and private study; Florence Mildred Rhodes, Royal Free Hospital; Alan Harvey Richardson, St. Thomas's Hospital; Norman Fairbank Smith and Cecil Henry Terry, Oxford University and St. Bartholomew's Hospital;

William James Walters, Cambridge University and Guy's Hospital; Hugh Pennefather Warren, London Hospital; Idwal Glynne Williams, St. Bartholomew's Hospital; Sidney Winnick, London Hospital; Geoffrey Winter, Birmingham University; Samuel Anthony Withers, Guy's Hospital; and Alfred Frank Wyatt, London Hospital.

UNIVERSITY OF GLASGOW.—The following candidates have passed the examination for the degrees of Bachelor of Medicine (M.B.) and Bachelor of Surgery (Ch.B.) in the subjects indicated—B., botany; Z., zoology; P., physics; C., chemistry:—

Alan Percy Agnew (Z., C.), Alexander Gardner Aitken (Z., C.), William Simpson Aitken (Z., C.), Daniel Edwin Alley (B.), Angus Alistair Bain (Z., C.), Alexander Baird (Z.), Adam Barr (Z.), Alexander Mitchell Beaton (Z.), Alexander Ronald Black (P.), John Thomas Blundell (Z.), Gavin Haddow Boyd (Z., C.), Alexander Orr Bruce (Z.), George Frederic Cables (Z.), Stewart Caldwell (Z., C.), Patrick Anderson Carrie (Z., C.), Alexander Chisholm (Z., C.), Douglas Hugh Clutterbuck (C.), Horace Collingbourne (C.), Archibald Robson Cook (B., Z., C.), William Davie (Z.), James Dawson (Z., C.), Joseph Dewar (Z.), Alexander Smith Dick (Z.), James Millar Duff (Z.), William Norman Duguid (Z.), Thomas Fletcher (Z., C.), John Cochrane Forsyth (Z., C.), Bruce Paterson Gardner (B., C.), Thomas Gibson (Z., C.), Robert Dick Gillespie (Z., C.), Charles Glen (Z., C.), George Garlach Graham (C.), Alexander Gray (Z., C.), James Lorimer Halliday (Z., C.), David Russell Hamilton (Z., C.), William Mason Hamilton (P.), David Henderson (Z., C.), Wesley Cope Holdsworth (Z., C.), Walter Houston (Z., C.), Alexander Deans Humble (B., P.), Jacob Hurwich (Z., C.), George Jamieson (C.), Lennox Matthew Johnston (Z., C.), William Livingstone Kennedy (Z., C.), David Alison Ker (Z., C.), William Patrick David Kerr (Z., C.), James Cowan Kirkwood (Z., C.), Daniel Lamont (Z., C.), John Lavelle (Z.), Alexander Logan, M.A. (B.), Alexander Lennox M'Adam (Z., C.), George M'Alpine (B., P., C.), George Hutton Macartney (Z., C.), Henry John M'Bride (Z., C.), Malcolm M'Neil M'Bride (B., P.), William Martin M'Cash (Z., C.), Alexander Mitchell M'Clure (Z., C.), James M'Court (B.), Robert M'Courtney (B.), Duncan Macdiarmid (Z., C.), James Macdonald (Z., C.), Thomas Simpson MacDonald (Z., C.), John M'Dougall (Z., C.), James Maclarlane (Airdrie) (Z., C.), Thomas John M'Kail (Z., C.), William M'Kendrick (Z., C.), Stewart Reid M'Kim (B., Z.), Oswald Thomas Maclaren (Z., C.), James M'Nair (Z., C.), Joseph Craig M'Naught (Z., C.), Roderick Montague Macpherson (Z., C.), Matthew Findlay Guthrie Main (Z.), Abraham Markson (Z., C.), Edin Ernest Miller (Z., C.), John Malcolm Lamont Mitchell (Z., C.), George William Murray (Z., C.), James Nairne (Z., C.), James Paton Neilson (C.), Malcolm Nicolson (Z., C.), George Strachan Park Noble (Z.), Archibald Little Orr (Z., C.), Thomas Core Porter (C.), Alexander Hunter Rankin (Z., C.), Peter Crawford Rankin (P.), James Reid (Z., C.), Joseph Francis Reilly (Z., C.), Cyril Gladstone Richards (Z.), Joseph Sachs (Z., C.), Wilfrid Henry Scott (Z., C.), Henry Edmund Seller (Z., C.), Herbert James Sheppard (Z., C.), Archibald Gordon Smith (Z., C.), David Croydon Smith (Z., C.), Andrew Snaddon (Z., C.), James Sneddon (C.), Francis Cyril Speechly (C.), Archibald Vernon Steen (Z., C.), Donald Stewart (B.), Donald Stewart (Z., C.), John M'Laughland Strang (Z., C.), William David Sutherland (Z., C.), Alexander Symon (Z., C.), Andrew Smith Taylor (Z.), Charles Noel Temple (Z.), William Lees Templeton (Z., C.), James Nisbet Tennent (Z., C.), David Wolfe Tobias (Z., C.), George Tudhope (Z., C.), John Walker Walker (B., P.), James Dunlop Whiteford (C.), Charles Edwin Whittet (Z., C.), Peter Andrew Wilson, M.A. (C.), William Wilson (Z., C.), John Wingate (Z., C.), John Wyllie, M.A. (Z., C.), and John Yule (Z., C.).

Women.—Annie May Alexander (Z.), Marion Bell Armstrong (Z., C.), Mary Baird (Z., C.), Margaret Bennett, M.A. (Z., C.), Elizabeth Margaret V. H. B. Bird (Z., C.), Margaret Watson Blackwood (Z., C.), Agnes Leggatt Duncan Bradford (Z., C.), Susan Struthers Bryce (C.), Lilias Elizabeth Barr Buchanan (Z.), Annie Burns Cameron (P., C.), Edith Chalmers (C.), Ellen Bell Cowan (Z.), Edith Margaret Davidson (Z.), Simone Denil (Z., C.), Isabella Gibson Dunlop (B.), Elsie Florence Farquharson, M.A. (Z., C.), Elizabeth Jardine Findlay (Z., C.), Christian Melville Fleming (Z., C.), Margaret Elizabeth Gibson (Z.), Muriel May Gilmour (Z., C.), Agnes Scott Glover (Z., C.), Mabel Scott Goudie (B., Z.), Mary Burns Grant (Z., C.), Christina Gray (Z., C.), Brünnhilde Mary Grieve (Z., C.), Agnes Brownlie Hart (Z.), Marion Pitcairn Hogg (B., P.), Isabel Edgar Russell Jeffrey (C.), Margaret Longwill Johnston (Z., C.), Jane Carrick MacDonald (Z., C.), Mary Johnston Macfarlane (Z., C.), Annie Isabel Christine Maclardy (C.), Alexandrena Miller Maclennan (Z., C.), Marie Josephine M'Naught (C.), Muriel Mary M'Walter (C.), Janet Dick Montgomery (Z., C.), Effie Niblock (Z., C.), Alice Janet Paton (B.), Joanna Thomson Rae (Z., C.), Isobel Reid (Z.), Kathleen Eleanor Hyde Rutherford (Z., C.), Mary Russell (Z., C.), Marguerite Linck Sclanders (Z., C.), Margaret Dorothy Lightbody Service (Z., C.), Catriona Sinclair (Z., P.), Elizabeth Helen May Slimmon (Z., C.), Alexandra Walker Smyllie, M.A. (Z., C.), Jane Edgar Stewart (Z., P., C.), Christina Smith Stoddart (Z., C.), Margaret Mavor Stuart (Z.), Dorothy Mary Summers (Z.), Helen Bruce Sutherland (Z., C.), Margaret Young Turnbull (Z.), Mary Carswell Walker (Z., C.), Mary Lyle Wilson (Z., C.), Helen Frances Wingate (Z., C.), and Agnes Hart More Young (Z., C.).

The following passed in the subjects indicated—A., anatomy; P., physiology; M., materia medica and therapeutics; Path., pathology:—

Carl Otto Anderson, M.A. (A.), Alexander Basil Austin (Path.), Roderick Bethune (M.), Alexander Black (M.), Donald Cameron Bowie (P., M.), John Bradford (Path.), Archibald Donald Brown (A., P.), Michael John Cabalane (M.), Thomas Watson Carstairs (P.), Malcolm Chalmers, M.A. (A.), Alexander Ebenezer Cochrane (M.), Hugh Auld Cochrane (M.), Alexander Conner Connell (A., P.), Edward Mitchell Erskine Cumming (A., P.), William Dempster, M.A. (M. Path.), John Campbell Dow (A., P.), Archibald Browning Smith Drysdale (M.), Kenneth Henry Dyke (M., Path.), Duncan Finlayson (M.), James Paton Fleming (M.), Thomas Fleming (M.), Thomas Forrest (M.), Allan Donald Fraser (A.), Kenneth John Alexander Gillanders (M.), William Hadden Gordon, M.A. (Path.), Adam Smith Goudie, M.A. (M.); Peter Fife Auchinache Grant (A., P., M.), James Smith M'Lean Gray (M.), John Gordon Harrower (M.), Andrew Henderson (M.), John Hislop (M.), Tom John Honeyman (Path.), Morris Hyman (M.), Edward Porteous Irving (Path.), John Irving (M.), Jacob Joels (M.), Robert Ebenezer Kerr (M.), William Hogarth Kerr, M.A. (M.), William Mackintosh Kerr (M., Path.), James Patrick Kilty (M.), Andrew Brown M'Aulay Lang, M.A. (Path.), George Lean, B.Sc. (Path.), James Liddell (M.), Jacob Lipschitz (M.), Frederick Richard Lubovius (Path.), William Wilson Lundie (Path.), Alan James Macartney (A., P.), Duncan MacColl (A., P.), Hugh Ernest M'Coll (M., Path.), Andrew Buchanan Macdonald (A., P.), Robert Tweedie M'Gibbon (M.), Arthur Daniel Clark M'Gowan (Path.), Thomas M'Gowan (M.), James Athole Campbell MacGregor (M.), Douglas Bower M'Intosh (Path.), John William Mackay, M.A. (M.), Donald William Morison MacKenzie (M., Path.), Robert Hugh M'Killop (Path.), James Graeme M'Kinna (A. M.), James Macalister Mackintosh M.A. (Path.), William Stanley Lones M'Leish (M.), John Macleod (A., P.), William M'Linden (M.), Findlay Kerr Macmillan (A., P.), Donald Macqueen (M., Path.), Allan Watt M'Rorie (M.), John Muil Melvin (M.), George Anderson Mitchell (Path.), William Napier (M.), John Nicolson, M.A. (A., P., M.), Isaac Ladipo Oluwole (A.), James Paterson (A., P.), James Walker Patterson (M., Path.), Norman Bligh Peacock (M.), George Pearson (M.), Robert James Peters (M.), John Browning Potter (M.), Rahmat Ullah Qureshi (A., P.), Ian Menteith Robertson (M.), John Joseph Robertson (M.), Frank Watt Sandeman (M., Path.), Thomas Robertson Sinclair (Path.), Clarence Lorraine Somerville (M.), Thomas Stark (A., P.), James Stewart (A., P.), Arch Sutherland Strachan, M.A., B.Sc. (M.), Joseph Turner Taylor (A.), James Joseph Treanor (M., Path.), James Churchwill Vaughan (M.), Alexander Ross Waddell (A., P.), James Livingstone Walker (M., Path.), William Andrew Walker (A., P.), Harold Douglas Wallace (M.), Hugh Wands (A., P.), Robert Wiggins (M.), George Macfeat Wishart (M.), and Robert Young (A., P.).

Women.—Annetta Gillies Turnbull Anderson (Path.), Ellen Davidson Anderson (A., P.), Mabel Nellie Blake (M., Path.), Grace Chatterton (M.), Margharita Mary Lamont Couper (M.), Grace Anderson Fleming (M.), Margaret O'Rourke Gallagher (Path.), Mary Brown Gillespie (Path.), Jane Evelyn Hanson (M.), Janet Whyte Hepburn (M.), Mary Reid Knight, M.A. (M.), Elizabeth Cochrane Loudoun (M.), Mary Jessie Macdonald (M.), Isabella Quarrier M'Fadzean (M.), Margaret Turner M'George (M.), May Elizabeth MacIver (Path.), Maud Elizabeth Drysdale Mackinnon (A.), Margaret Gardner M'Vey (M.), Florence Frances Mitchell Milne (A., P.), Mercedes Margaret Morton (Path.), Elizabeth Park Young Paterson (M.), Vida Johnston Perry (A., P.), Margaret Innes Prangnell (A., P.), Margaret Nelson Robertson (P.), Agnes Petrina Routledge (M.), Marjory Mary Scanlan (A., P.), Katherine Scott (A., P.), Margaret Marion Catherine Steedman (M.), Dorothea Helen Suttie (M.), and Lydia Ida Huber Torrance (M.).

The following passed in Medical Jurisprudence and Public Health of the Fourth Professional Examination (New Medical Ordinance):—

John William Waddell Baillie, Joseph Edwards Bannen, William Moore Cameron, M.A., Robert Cunningham, David Heard Frederick William Hebblethwaite, George Mundell Hetherington, Henry Fielden Hollis, James Robert Riddell Holms, James Neil Jamieson, M.A., Kenneth M'Alpine, Neil MacKillop, James Macalister Mackintosh, M.A., Humphrey Robertson, M.A., Henry Buchan Sergeant, Andrew Wauchope Smith, and John Thomas Wylie.

Women.—Janetta Margaret Alexander, Winnifred Jane Crawford, Margaret Hutchison Glen, Alice Julia Marshall, May Isabella Turner Reid, Marion Watson, and Mary MacLean Weir, M.A.

The following passed in Medical Jurisprudence and Public Health of the Third Professional Examination (Old Medical Ordinance):—

Alexander George Brand, John MacDougall Clark, William Hadden Gordon, M.A., Eduardo Guillermo Sanchez Hall, Tom John Honeyman, Andrew Brown M'Aulay Lang, M.A., Arthur Daniel Clark M'Gowan, Alexander Benham Stich, B.Sc., and John Allan White.

The following candidates passed with distinction in the subjects indicated:—

In Zoology—Alan Percy Agnew, Mary Baird, Elsie Florence Farquharson, M.A., Thomas Fletcher, Robert Dick Gillespie, James Lorimer Halliday, Mary Johnston Macfarlane, Alexandrena Miller Maclennan, James M'Nair, John M'Laughland Strang, Mary Carswell Walker, Helen Frances Wingate, and John Wyllie, M.A. In Chemistry—Alan Percy Agnew, James Lorimer Halliday, Margaret Longwill Johnston, George William Murray, John M'Laughland Strang, William Lees Templeton, Helen Frances Wingate, and John Yule. In Anatomy—Archibald Donald Brown. In Physiology—Alan James Macartney and Thomas Stark. In Medical Jurisprudence and Public Health—William Moore Cameron, M.A., James Neil Jamieson, M.A., Andrew Brown M'Aulay Lang, M.A., James Macalister Mackintosh, M.A., and Mary MacLean Weir, M.A.

QUEEN'S UNIVERSITY OF BELFAST.—At examinations held recently the following degrees and diplomas were conferred:—

M.D.—Samuel H. Davison and Frederick C. Mann.

M.B., B.Ch., and B.A.O.—Eileen M. Bell (second-class honours), David Corry, John Cullenan (second-class honours), Charles F. Davey, Samuel J. W. Donald, James E. Finlay, Mary E. Henry, Mary M. Keirns, John M. McCormack, James C. McMillan (second-class honours), Joseph R. M. Mackenzie, John F. W. Meenan, William N. Montgomery, and Robert L. Sinclair.

Diploma in Public Health.—Alfred M. Elliott (*in absentiâ*), Philip J. Gaffikin (*in absentiâ*), Herbert M. Jackson, and Robert J. Morgan.

HUNTERIAN SOCIETY.—The annual general meeting will be held at 1, Wimpole-street, W., on Wednesday next, April 26th, at 8.30 P.M. The principal business will be the election of officers for next session.

Parliamentary Intelligence.

HOUSE OF COMMONS.

WEDNESDAY, APRIL 12TH.

The Medical Profession and the War.

Sir JOHN LONSDALE asked the Under Secretary for War whether he was aware that there were a number of practising physicians and surgeons above the age of 45 who would be willing to volunteer for special and general service at home, and thus enable the War Office to free active service men for work at the front; and whether the War Office would officially invite all medical men, without limitation of age, to offer their services for the period of the war under a scheme which would ensure proper recognition and due consideration of the special qualifications of practitioners who volunteered.—Mr. TENNANT replied: Medical men between the ages of 45 and 55 are being employed as commissioned officers for general service in the United Kingdom. Medical men over 55 may offer their services for local employment to the general officer commanding-in-chief of the command in which they are living or in which they desire to do duty with the troops. I think the honourable baronet and my medical advisers are really at one in this matter. In other words, the policy should be that medical men of more advanced years render the country better service by undertaking the care of the civilian population and thus setting free those of military age who are physically fit for duty at home or abroad.

Sir JOHN LONSDALE: Is the right honourable gentleman aware that the medical profession are looking for a clear and definite lead from the War Office in this matter, which they have not had up till now?—Mr. TENNANT: I am surprised to hear my honourable friend say that. We have endeavoured to carry out the policy which he advocates to the best of our ability, and we are continuing to do so.

Mr. RONALD MCNEILL asked the right honourable gentleman whether, with a view to economising the supply of medical men available for the army, he would take steps to provide that general practitioners be, so far as possible, employed in part-time work in hospitals or in looking after the health of troops quartered in the neighbourhoods where such practitioners lived, so as to release for duty abroad men who had volunteered for whole-time service, thus obviating the necessity for asking an unnecessary number of men to take commissions in the Royal Army Medical Corps, whereby the supply of doctors for the civil population at home was in danger of being unduly depleted.—Mr. TENNANT answered: General practitioners are already being largely employed in local military work. Every effort is being made to protect the needs of the civil population for adequate medical attendance, and in this connexion the War Office is receiving the advice and assistance of representatives of the civil medical profession and of the various Government departments concerned.

The Royal Army Medical Service.

Mr. RONALD MCNEILL asked the Under Secretary for War whether he would appoint an independent committee to examine into and report upon the organisation and working of the Army Medical Service at home and abroad.—Mr. TENNANT replied: I cannot undertake action which in my view could only have the effect of dislocating and perhaps disorganising a most efficient piece of mechanism.

Mr. MCNEILL: Is the right honourable gentleman aware that a considerable number of the officers of the Royal Army Medical Corps practising at the front endorse the suggestions which I ventured to make some weeks ago in the House?—Mr. TENNANT: As the honourable gentleman has not thought it right to send me the letters, naturally I could not have the information which he has acquired.

Mr. MCNEILL asked whether the right honourable gentleman was aware that some of the most eminent specialists in the various branches of surgery had been for a long time during the war employed in field ambulances or otherwise where their special qualifications were wasted; and whether it was proposed to take any steps to ensure that doctors with special experience in different branches of medicine and surgery who had joined the Royal Army Medical Corps should be utilised to the best advantage.—Mr. TENNANT answered: Our supply of efficient operating surgeons in our military hospitals at home and abroad is fully adequate. It is necessary that a certain number of younger surgeons should do duty with field ambulances, and they are employed with those units. Every effort is made to utilise the services of medical men joining the Royal Army Medical Corps for such duties as their professional qualifications best fit them, but it is impossible to allow each individual to select the work which he considers himself most competent to undertake.

Mr. MCNEILL: Has the right honourable gentleman observed that my question says that some of the most eminent specialists in the various branches of surgery were so employed, not the younger officers, as he says in his reply, and is he prepared to deny that eminent specialists in surgery have been employed in very inferior work?—Mr. TENNANT: I am quite prepared to believe that eminent specialists have occasionally, when they are employed abroad, to do somewhat trivial and menial duties. That must be part of every campaign.

Mr. MCNEILL: Not at all.—Mr. TENNANT: I do not agree with my honourable friend. I think it is absolutely inevitable in the ordinary routine of carrying on a great campaign that it may fall to the lot of the most eminent to do most trivial duties. We retain the services of these eminent specialists, and if we have to employ them in that way occasionally I am sorry, but it is part and parcel of the difficulty of carrying on a great campaign.

Precautions against Malaria at Salonica.

Lord HENRY CAVENDISH-BENTINCK asked the Under Secretary for War, in view of the fact that malaria was prevalent in the neighbourhood of Salonica during the summer months, whether the medical authorities were taking steps to safeguard the health of our troops by exterminating the mosquitoes which bred in the adjacent marshes.—Mr. TENNANT replied: The authorities at Salonica are fully alive to the importance of the matter which the noble lord presses on my attention and they are taking the necessary steps.

Recruits and Hernia.

Replying to Mr. JOWETT, Mr. TENNANT said: Carefully selected men suffering from slight hernia, if properly fitted with a truss, may be passed for general service in the army. It is not anticipated that active service will incapacitate or harm these men.

Sickness at Oswestry Camp.

Sir FREDERICK CAWLEY asked the Under Secretary for War what were the arrangements for dealing with cases of sickness at the Oswestry camp in regard to medical staff and hospital accommodation respectively; and whether he was aware that great dissatisfaction existed as to the provision for dealing with the abnormal number of cases at this camp.—Mr. TENNANT said in reply: When I answered my honourable friend on April 6th I was under the impression that he was referring to Prees Neath camp, and the figures which I gave had reference to that camp and not to the adjoining Oswestry camp. The number of admissions to hospital at this camp from Oct. 1st to March 31st was 1754, and of those admitted 13 died, 3 of them as a result of accidents. The number of recruits training in this camp was 8500 and the total strength is 11,000. The medical arrangements at this camp are, in the opinion of the Deputy-Director of Medical Services and also of that of the senior medical officer of the camp, adequate. A medical officer is attached to each battalion. The hospital is a temporary one with 100 beds. There are in all 11 medical officers attached to the camp, 8 regimental officers and 3 officers doing duty at the hospital. In addition there are 4 medical officers belonging to the Welsh Field Ambulance, which are stationed at this camp for training. Their services are always available if required.

Massage in Military Hospitals.

Major CHAPPLE asked the Under Secretary for War whether specialists in massage who held colonial qualifications were being denied employment in military hospitals because they did not hold an Almeric Paget diploma; whether they were also being denied the right to sit for examination for this diploma unless they took the full six months' course; and whether he had any evidence that this spirit and policy were being resented by the oversea dominions.—Mr. TENNANT wrote in reply: Specialists in massage who hold colonial qualifications are not being denied employment in military hospitals because they do not hold an Almeric Paget diploma. I am, in fact, informed that there is no such thing as an Almeric Paget diploma. Six months' training is required before a masseuse can be accepted, unless her education took place some time ago. This is the rule for the qualification of masseuses in civil life. The answer to the last part of the question is in the negative.

Soldiers and Hospital Treatment.

Major ASTOR asked the Under Secretary for War whether treatment given to soldiers in hospital was applicable in the case of all kinds of diseases or wounds, and whether such treatment was continued until a cure was effected or had become clearly impossible.—Mr. TENNANT (in a written answer) replied: Hospital treatment is continued until a cure is effected or until it is obvious that the soldier will not be medically fit to remain in the service. In no circumstances is a soldier discharged from hospital (except to special institutions) unless he is able to leave without detriment to his health.

The Board of Control.

Mr. H. SAMUEL (Home Secretary) informed Mr. KING that the work of the Board of Control had not been materially

reduced by the handing over to the War Office of certain asylums.

Mr. KING asked the right honourable gentleman in what way were Lunacy Commissioners specially qualified to undertake the supervision of war hospitals; whether such duties withdrew them from their ordinary functions; whether Lunacy Commissioners so engaged were receiving additional pay from the War Office; what amount of work and control had been vested in them; whether they were subject to the War Office or Home Office or both these departments in such duties; what was the number of these hospitals under the supervision of the Lunacy Commissioners; and whether all the previous inmates had been removed from such hospitals.—Mr. SAMUEL wrote in reply: The two Commissioners whose services have been temporarily lent by the Board of Control to the War Office are both medical men with high medical qualifications and wide experience in hospital organisation and administration. It is mainly through their advice and action that the Board has been able to place at the disposal of the War Office nearly 20,000 well-equipped beds for sick and wounded soldiers. Their duties in this connexion have for the time being, to a considerable extent, withdrawn them from their ordinary functions. They are not receiving any payment from the War Office. The hospitals as soon as they were organised became military hospitals entirely under the control of the military authorities, but the latter still continued to have the advantage of the advice and assistance of the Commissioners in question in certain matters of administration that are from time to time referred to them. The number of hospitals so far provided by the Board of Control is 13, and another will be ready shortly. The previous inmates have been removed from the hospital except a small number of patients with mild symptoms, who have been retained for the purpose of carrying on the work on the farms attached to the hospitals, and are mostly housed in the outlying buildings.

THURSDAY, APRIL 13TH.

Royal Commission on Venereal Diseases.

Major ASTOR asked the Prime Minister whether it was proposed this session to give effect by administration and legislation to any of the recommendations of the Royal Commission on Venereal Diseases.—Mr. ASQUITH answered: The report is now under the consideration of the departments concerned, and to-morrow the President of the Local Government Board is receiving an important deputation on the subject. It is the intention of the Government to deal as expeditiously as possible with this matter.

The Wittenberg Camp.

Mr. GILBERT asked the Secretary for Foreign Affairs to state the number of British prisoner camps in Germany and how frequently they were visited on behalf of His Majesty's Government; and whether, in view of the recent report on the prisoners' camp at Wittenberg, he could arrange for more frequent visits to be made to all camps and for the reports received on the same to be published immediately they were received.—Sir EDWARD GREY replied: According to an official statement by the Prussian Ministry of War, which was issued to the press on Feb. 14th last, there are in Germany 25 camps for officer prisoners, 46 for rank and file, and 42 lazarettes. Nearly all the camps and a considerable number of the lazarettes have been visited by the United States Embassy at Berlin, the more important on a number of occasions. When complaints are received with regard to a camp the United States Ambassador at Berlin is requested to send a member of his staff to inspect it. The reports on camps are issued to the press as soon as they are received. The staff of the United States Embassy at Berlin is being increased by four medical men to enable more frequent visits to be paid to camps. The German authorities refused to permit a visit to Wittenberg during the period covered by the recent report, on the ground of infection. ..... The last report from the United States Ambassador at Berlin on this camp is dated on March 10th, and was issued to the press on March 28th. The report states among other things that there was a decided improvement in conditions since the previous reports in November and January, and that the commandant had been changed.

Sir HENRY DALZIEL: Were the Foreign Office aware of the serious facts of this case at the time they occurred and what steps did they take to deal with them?—Sir EDWARD GREY: As the House will gather from the report, we did not know the full facts until quite recently when the two doctors had been released from the camp. With regard to the steps taken, we pressed continually for visits of inspection to the camps and reports on the camps whenever we heard that there was trouble. The right honourable gentleman will realise from the answer I have just given that in the Wittenberg case the German authorities refused to permit visits to Wittenberg during the period covered by the recent report on the ground of infection. Therefore we could not know.

Treatment of Consumptive Soldiers.

Major ASTOR asked the Under Secretary for War how many military and Territorial hospitals had verandahs built for the purpose, *inter alia*, of providing treatment for consumptive soldiers; and whether he could state approximately the number of patients who could be accommodated and treated on these verandahs.—Mr. TENNANT replied: Soldiers suffering from pulmonary tuberculosis are discharged from the service and admitted to sanatoria under arrangements made with the Insurance Commissioners and the Local Government Board. It is true that a special type of hut has been designed with verandahs for the treatment of some cases, though not necessarily for consumptive patients, but I have no data as to the number of patients who could be accommodated in existing verandahs.

Steel Helmets for the Troops.

Colonel MCCALMONT asked the Under Secretary for War whether he was aware that the supply of steel helmets did not yet provide for every soldier whose duty took him to the trenches; and whether he could state how soon a sufficient number would be available.—Mr. TENNANT said in reply: I have acquainted myself with the state of the supply. I do not propose to inform this House or the enemy about it in detail, but the active resumption of hostilities will not find the troops in the trenches unprovided in this respect.

Colonel MCCALMONT: Can the right honourable gentleman assure the House that there is no diminution in the supply and that it is being kept up steadily?—Mr. TENNANT: Yes, the supply is, on the contrary, being accelerated.

The Notification of Infectious Diseases.

On a motion to recommit the Local Government (Emergency Provisions) Bill,

Mr. BOYTON urged the Local Government Board to reconsider the decision to cut down the fee to medical men for notification of a case of infectious disease from 2*s*. 6*d*. to 1*s*.

Mr. HAYES FISHER (Parliamentary Secretary to the Local Government Board) said that he had consulted the President on the subject, but his right honourable friend had held out no hope of foregoing the clause. The reduction in the fee was an economy asked for at all events during the war, and he could not assent to the suggestion that the reduction should not be made.

The subject then dropped.

MONDAY, APRIL 17TH.

Steel Helmets for the Troops.

Replying to Mr. ANNAN BRYCE, Dr. ADDISON, Parliamentary Secretary to the Ministry of Munitions, said: The steel helmets of which large quantities have already been supplied to the British Forces in France and of which adequate supplies are assured, possess higher protective powers than the French pattern. It is desirable that a uniform design should be adhered to, and I am not aware that steel of the requisite standard can be obtained in France. I may point out that it is most important to maintain the reliance which, I am informed, our troops now place in the helmets.

The Wittenberg Camp.

Answering Mr. MALCOLM, who put a question relating to affairs in the Wittenberg camp during the months when typhus was prevalent Lord ROBERT CECIL (Under Secretary for Foreign Affairs) said: The Germans permitted no kind of communication, either by letter or orally, as to the condition of Wittenberg during the months in question, and the Government had, I need not say, no suspicion of the horrors that were going on there or of the gross and criminal cowardice of the German medical staff in abandoning their duties to those under their charge. Neither our Allies, whose prisoners in the camp were far more numerous than ours, nor we demanded independent medical examination of the camp, and on behalf of the Government I can only express profound regret that we so under-estimated the brutality of our enemies. It is only right to say that we have no reason to suppose that other typhoid-infected camps in Germany were treated in the same way.

German Ill-treatment of Sick Prisoner.

Captain DOUGLAS HALL asked the Home Secretary whether Private A. C. Tulley, Royal Marines, with 10 years' service, died at the Barrack Hospital, Millbank, recently, weighing only five stone; whether he was aware that this man went out to Antwerp weighing about 14 stone, and was there taken prisoner by the Germans; that he was confined at Doberitz and, by statements received, was starved, ill-used, and knocked about, and finally sent back to England about the middle of February in a dying condition to the Millbank Hospital where he died within a fortnight of his reception; whether representations would be made to the American Ambassador with a view to alleviating the brutality and ill-treatment of other prisoners of war in this camp; and whether he would state how many prisoners of war returned from this camp had since died in England and

the cause of their death as diagnosed by the medical authorities here.—Mr. HERBERT SAMUEL answered: I am informed that the statements in the question are substantially correct, but there is no record of Private Tulley's weight at the time of death. It appears from his statement that he was confined in the camp at Doberitz and that after working in the wet he had no means of drying his clothes and could get no underclothes. The men were covered with lice. In July, 1915, he got rheumatic fever through going on daily fatigue duty, getting wet through and having no change. He was sent to hospital, and after five weeks was convalescent and was sent to another camp called Dyrotz about seven kilometres from Doberitz. He had to carry all his kit on the march and broke down, and was never well after that. A little later he was put into hospital at Doberitz, where he had no treatment at all and he had to depend upon an English prisoner, one of the patients. They had no drugs. When he arrived in this country he was in an advanced state of consumption and extremely emaciated, and he died in hospital a fortnight after his arrival. The Medical Board who reported upon his condition stated that it was due to exposure, insufficient food and clothing, whilst a prisoner in Germany. Tulley himself stated that the conditions in camp had much improved before he left it, and other reports confirm this. The improvement seems to have resulted from the efforts of the American Ambassador. There is no record of any other prisoners of war released from Doberitz camp having died since their return to this country.

TUESDAY, APRIL 18TH.

Medically Unfit Prisoners of War.

Mr. MALCOLM asked the Under Secretary for Foreign Affairs whether he could now state how many British civilian prisoners had been passed by German doctors as medically unfit and therefore qualified for repatriation; and what had been the result of the fresh steps announced by him to expedite the exchange of prisoners of this class.—Lord ROBERT CECIL said in reply: The answer to the first part of the question is in the negative. We have so far received no reply from the German Government to the proposals we have made to them indicated in the second part of the question.

Mr. MALCOLM asked the Under Secretary of State for War whether he could now state or circulate the categories of diseases which would qualify British prisoners of war suffering therefrom to be interned in Swiss sanatoria; whether these categories would be identical with those agreed upon in February last between France and Germany; and when the panels of neutral doctors would begin their visitations of prisoner camps in Germany and England, with a view to ascertaining how many prisoners from both countries were qualified by the nature of their infirmities to take advantage of the hospitality offered by the Swiss Government.—Mr. TENNANT answered: A definite agreement as to the diseases which will qualify British prisoners of war for internment in Switzerland has not yet been reached with the German Government. The desire is that the category of disabilities shall be the same as that which is now in force between France and Germany. It is hoped the Swiss medical men will be prepared to commence tours of inspection in British and German camps as soon as an agreement has been reached with Germany.

Women in Munition Factories.

Mr. HERBERT SAMUEL informed Lord HENRY CAVENDISH-BENTINCK that in a new General Order effect would be given to the recommendation of the Health of Munition Workers Committee that the weekly hours of work for women and girls on munitions should not exceed the normal legal limit of 60.

Vacancies.

For further information regarding each vacancy reference should be made to the advertisement (see Index).
When the application of a Belgian medical man would be considered the advertisers are requested to communicate with the Editor.

BATH, WINSLEY SANATORIUM.—Assistant Resident Medical Officer, unmarried. Salary £250 per annum, with board, residence, and laundry.

BIRMINGHAM AND MIDLAND EYE HOSPITAL, Church-street, Birmingham.—Resident Surgical Officer. Salary from £200 to £300 per annum, with board, residence, &c.

BOURNEMOUTH HOSPITAL FOR SICK AND WOUNDED, Boscombe.—House Surgeon for six months. Salary £125 per annum, with board, lodging, and washing.

BRIGHTON COUNTY BOROUGH ASYLUM, Haywards Heath.—Temporary Resident Assistant Medical Officer. Salary 25 guineas a month.

BRISTOL ROYAL INFIRMARY.—House Physicians and House Surgeons. Salary at rate of £120 per annum, with board, apartments, and laundry.

BURNLEY, VICTORIA HOSPITAL.—Female House Surgeon. Salary £160 per annum, with residence, board, and washing.

BURY INFIRMARY.—Senior House Surgeon. Salary £250 per annum, with board, residence, and washing.

BUXTON, DERBYSHIRE, DEVONSHIRE HOSPITAL.—Assistant House Physician. Apartments, board, laundry, and salary as arranged.

CHESTERFIELD AND NORTH DERBYSHIRE HOSPITAL.—Second House Surgeon. Salary £150 per annum, with board, apartments, and laundry.

COBHAM, SURREY, SCHIFF HOME OF RECOVERY, Knowle Hill Park.—Resident Surgical Officer for six months. Salary at rate of £200 per annum, with board, lodging, and washing.

FEDERATED MALAY STATES GOVERNMENT.—Female Medical Officer. Salary £350 per annum. CENTRAL LUNATIC ASYLUM: Assistant Superintendent. Salary £400 per annum, with free quarters.

LEEDS PUBLIC DISPENSARY.—Female Resident Medical Officer. Salary £130 per annum, with board, residence, and laundry.

MANCHESTER NORTHERN HOSPITAL FOR WOMEN AND CHILDREN, Parkplace, Cheetham Hill-road.—Female House Surgeon. Salary £120 per annum, with apartments and board.

MANCHESTER ROYAL INFIRMARY.—Resident Medical Officer and Resident Surgical Officer. Salary £225 per annum each. Also Assistant Resident Surgical Officer, Accident Room House Surgeon, and Resident Medical Officer (Central Branch). Salary £200 per annum in each case.

NEW HOSPITAL FOR WOMEN, Euston-road, N.W.—Female Temporary Assistant Surgeon for six months.

NEWCASTLE-UPON-TYNE, ROYAL VICTORIA INFIRMARY.—Four Resident House Physicians, Four Resident House Surgeons, Resident Accident Room House Surgeon, Resident House Surgeon to Aural and Ophthalmic Department, Resident House Surgeon to Skin and Gynæcological Department, and Resident House Surgeon to Out-patient Dressing Department.

PUTNEY HOSPITAL, Lower Common, S.W.—Resident Medical Officer. Salary £150 per annum, with rooms, board, and laundry.

READING, ROYAL BERKSHIRE HOSPITAL.—House Surgeon for six months. Salary £250 per annum, with apartments, board, and washing.

ROCHESTER, ST. BARTHOLOMEW'S HOSPITAL, Kent.—Senior Resident House Surgeon. Salary at rate of £300 per annum.

SALISBURY GENERAL INFIRMARY.—Assistant House Surgeon, unmarried. Salary £100 per annum, with apartments, board, lodging, and washing.

SHEFFIELD, JESSOP HOSPITAL FOR WOMEN.—Female Junior House Surgeon, unmarried. Salary £80 per annum, with board, residence, and laundry.

SHEFFIELD ROYAL INFIRMARY.—House Physician. Salary £120 per annum, with board and residence.

SOUTHAMPTON FREE EYE HOSPITAL.—House Surgeon. Salary £100 per annum, with board, lodging, and laundry.

VENTNOR, ISLE OF WIGHT, ROYAL NATIONAL HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST.—Assistant Resident Medical Officer.

WEST HAM AND EASTERN GENERAL HOSPITAL, Stratford, E.—House Physician.

THE Chief Inspector of Factories, Home Office, London, S.W., gives notice of a vacancy for a Certifying Surgeon under the Factory and Workshop Acts at Acle, in the county of Norfolk.

Births, Marriages, and Deaths.

BIRTHS.

FAULKNER.—On April 14th, at The Rectory, Stanford-le-Hope, Essex, the wife of Captain Cyril D. Faulkner, R.A.M.C., of a son.

MAY.—On April 12th, at The White House, Sonning, Berks, to Dr. and Mrs. Norman May, a son.

WILLIAMS.—On April 12th, at Bankside Nursing Home, Hendon, Nina (née Humphreys), the wife of Captain Charles Eustace Williams, R.A.M.C., British Expeditionary Force, France, of a daughter.

MARRIAGES.

CRAWFORD—JENNY.—On April 12th, at Christ Church, Woburn-square, London, Thomas Maitland Crawford, Lieutenant, R.A.M.C., to Mabel Gertrude Louise, only daughter of the late Jacques Jenny and Mrs. Jenny, of London.

MARTIN—GLADSTONE.—On April 3rd, at St. Paul's Church, Valetta, Malta, Captain James Sackville Martin, R.A.M.C., to Florence, eldest daughter of the late C. E. Gladstone, Bengal Civil Service, and Mrs. Gladstone, Roseneath, Jersey.

WILSON—MOTTERSHALL.—On April 12th, at the Church of St. Bartholomew the Great, London, Walton Ronald Wilson, Lieutenant, R.A.M.C., to Emily Constance Mottershall, niece of Mr. and Mrs. Walter Southern Hunt, of Eastbourne.

DEATHS.

BALL.—On April 10th, Lieutenant Malcolm E. Ball, M.B. Lond., R.A.M.C.

DONALDSON.—On April 7th, 1916, at his residence, 23, Eaton-square, Terenure, Co. Dublin, Robert Donaldson, M.R.C.S. Eng., J.P., late of Fort Hill, Castle Shane, Co. Monaghan.

PRALL.—On April 5th, at Mhow, India, Cedric Barkeley Prall, Lieutenant-Colonel, I.M.S., aged 44 years.

SPENDER.—On April 14th, at Marlborough-buildings, Bath, J. K. Spender, M.D. Lond., aged 86 years.

STEVENS.—On April 13th, at Southampton, after a long and painful illness, George Stevens, F.R.F.P.S. Glasg., late of Norton, Suffolk, aged 75 years.

N.B.—A fee of 5s. is charged for the Insertion of Notices of Births, Marriages, and Deaths.

Notes, Short Comments, and Answers to Correspondents.

MEDICAL MEN AND CORONERS' JURIES.

AT a recent inquest at Reading a coroner's jury thought fit to censure a medical man who had not attended immediately when summoned, his conduct being ascribed to "money-grubbing," with the added suggestion that he "might be a German." Dr. F. W. Stansfield, writing to the *Reading Standard*, puts the medical man's side of this often-raised question so clearly that the following passage from his letter deserves quotation: "A medical man is as much entitled to dispose of his services, for money or otherwise, in any way that he may choose as any other citizen." If it were not so, the writer adds, to enter the medical profession would be to submit to slavery, and would be the act of a lunatic. He further points out that those persons, rich or poor, who pay their medical attendants promptly and without grumbling, have some claim for consideration in return, and that the medical man cannot justly be blamed for giving the preference to them when there are several claims upon his time. This, we may add, would probably be the course adopted in parallel circumstances by the members of a coroner's jury as men of business and in the ordinary exercise of their trades. A juror, for example, who dealt in food, would not feel called upon to supply the necessaries of life gratis to a poor applicant, and would even more readily realise that it was undesirable to do so if the goods had already been ordered by one of his regular customers. The matter is sometimes referred to as an issue between "the medical profession and the public," and it may justly be pointed out that the public includes others besides the deceased person whose death happens to form the subject of an inquest. Dr. Stansfield sums the matter up by saying that a man should not be insulted who has committed no crime, and who "was only doing his duty in giving his services first to those who had a legal claim to them at that particular time."

"QUIDOS" CORK LIFE-SAVING APPLIANCES.

IN THE LANCET of March 14th, 1914, p. 800, we noticed the "Quidos" cork sanitary cushion, of which Mr. Leoline Edwards (81, St. Margaret's-road, Twickenham) is the inventor. He now calls our attention to various forms of life-saving apparatus—deck-chairs, cushions, and life-belts and waistcoats—stuffed with the prepared "Quidos" cork, the claim made for all of them being that they can be used or worn on deck in the normal way and become valuable life-saving apparatus in the case of shipwreck. An ingenious contrivance is the life-saving scarf, in form like a ladies' boa, which is easily adjusted round the body of the wearer if warmth is required, or can be rolled up into a soft cushion or pillow. We presume that the buoyancy of the cork fabric is sufficient in the amounts used to support the wearer in water.

VITAL STATISTICS OF BARBADOS.

THE Blue-book of Barbados for the year ended March 31st, 1915, has recently been presented to Parliament. The total estimated population of the colony is given as 176,397 (74,476 males and 101,921 females), an increase of 3038 on the previous year. The birth-rate per 1000 in 1914 was 37·4, as against 31·9 in 1913, and the death-rate was 36·5 per 1000, as against 21·3. Illegitimate births numbered 4092, or 62·4 per cent. of the total births. The burials of children under a year old numbered 2641, giving a rate of 403 per 1000 births, as against 213 per 1000 in 1913 and 416 per 1000 in 1912. The admissions to the General Hospital in 1914 totalled 2980 (daily average of patients 147), and there were 271 deaths. The out-patients during the year numbered 27,738. At the lazaretto there were 14 admissions, 2 discharges, and 11 deaths, leaving 121 inmates at the end of the year. An Act has been passed by the legislature providing for the compulsory segregation of any supposed leper found in a public place, if proved to be such, with certain concessions for isolation in private under regulation. At the lunatic asylum the daily average number of patients increased from 399 in 1913 to 424 in 1914; the admissions numbered 114, the discharges 51, and the deaths 91.

AN INGENIOUS PAPER FASTENER.

A PAPER fastener which dispenses with pins, wire clips, and similar contrivances, and thereby does away with the damage to fingers and nails with which most of us are familiar, has a distinct claim on consideration. The "Kibi" fastener is supplied by the Kingsway Commercial Association, Limited, of Windsor House, Kingsway, London, W.C. It is a form of punch which operates by separating, not punching out, a neat triangular opening in the papers to be attached to each other; the separated portion is slipped by the action of the punch through a slit that is made at the same time, the whole being accomplished instantaneously by the closing of the handles of the instrument, which resembles a pair of grips, and measures roughly 5 inches by 2½ inches. Just those papers which require to be permanently attached are particularly adapted to the "Kibi," whilst the fastening can easily be undone when desired. The instrument is nickel plated, and costs 17*s.* 6*d.*, post free.

COMMUNICATIONS not noticed in our present issue will receive attention in our next.

Medical Diary for the ensuing Week.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.

Course of Lectures on the Anatomy of the Human Body, for First-aid and Ambulance Students (open to all members of ambulance companies and first-aid classes):—

WEDNESDAY AND FRIDAY.—5.30 P.M., Prof. A. Keith. 4 P.M. to 7 P.M., Exhibition of Anatomical Preparations and Specimens in the Theatre on lecture days, and between 10 A.M. and 5 P.M. in the Hall of the Museum on the following day.

POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.

TUESDAY.—2 P.M., Medical and Surgical Clinics. X Rays. Mr. Addison: Operations. Dr. Banks Davis: Diseases of the Throat, Nose, and Ear. Dr. Pernet: Diseases of the Skin.

WEDNESDAY.—10 A.M., Dr. Saunders: Diseases of Children. Dr. Banks Davis: Operations of the Throat, Nose, and Ear. 2 P.M., Medical and Surgical Clinics. X Rays. Mr. Pardoe: Operations. Dr. Simson: Diseases of Women.

THURSDAY.—2 P.M., Medical and Surgical Clinics. X Rays. Mr. Gray: Operations. Mr. B. Harman: Diseases of the Eye.

FRIDAY.—10 A.M., Dr. Simson: Gynæcological Operations. 2 P.M., Medical and Surgical Clinics. X Rays. Mr. Addison: Operations. Dr. Banks Davis: Diseases of the Throat, Nose, and Ear. Dr. Pernet: Diseases of the Skin.

SATURDAY.—10 A.M., Dr. Saunders: Diseases of Children. Dr. Banks Davis: Operations of the Throat, Nose, and Ear. Mr. B. Harman: Eye Operations. 2 P.M., Medical and Surgical Clinics. X Rays. Mr. Pardoe: Operations.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY.—Clinics:—10.30 A.M., Surgical Out-patients (Mr. B. Gillespie). 2.30 P.M., Medical Out-patients (Dr. T. R. Whipham): Gynæcological Out-patients (Dr. Banister). 3 P.M., Medical In-patients (Dr. R. M. Leslie).

TUESDAY.—2.30 P.M., Surgical Operations (Mr. Carson). Clinics:—Medical Out-patients (Dr. A. G. Auld); Surgical Out-patients (Mr. Howell Evans); Nose, Throat, and Ear Out-patients (Mr. C. H. Hayton). Radiography (Dr. Metcalfe). 3.30 P.M., Medical In-patients (Dr. A. J. Whiting).

WEDNESDAY.—Clinics:—2.30 P.M., Throat Operations (Mr. C. H. Hayton). Children Out-patients (Dr. T. R. Whipham); Eye Out-patients (Mr. R. P. Brooks); Skin Out-patients (Dr. H. W. Barber). 5.30 P.M., Eye Operations (Mr. R. P. Brooks).

THURSDAY.—2.30 P.M., Gynæcological Operations (Dr. A. H. Giles). Clinics:—Medical Out-patients (Dr. A. J. Whiting); Surgical Out-patients (Mr. Carson); Radiography (Dr. Metcalfe). 3 P.M., Medical In-patients (Dr. R. M. Leslie).

FRIDAY.—2.30 P.M., Surgical Operations (Mr. Howell Evans). Clinics:—Medical Out-patients (Dr. A. G. Auld); Surgical Out-patients (Mr. B. Gillespie); Eye Out-patients (Mr. R. P. Brooks).

THE THROAT HOSPITAL, Golden-square, W.

MONDAY.—5.15 P.M., Special Demonstration of Selected Cases.

THURSDAY.—5.15 P.M., Clinical Lecture.

For further particulars of the above Lectures, &c., see Advertisement Pages.

EDITORIAL NOTICES.

IT is most important that communications relating to the Editorial business of THE LANCET should be addressed *exclusively* "TO THE EDITOR," and not in any case to any gentleman who may be supposed to be connected with the Editorial staff. It is urgently necessary that attention should be given to this notice.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this office.

Lectures, original articles, and reports should be written on one side of the paper only, *and when accompanied by blocks it is requested that the name of the author, and if possible of the article, should be written on the blocks to facilitate identification.*

Letters, whether intended for insertion or for private information, must be authenticated by the names and addresses of their writers—not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or news paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale, and advertising departments of THE LANCET should be addressed "To the Manager."

We cannot undertake to return MSS. not used.

MANAGER'S NOTICES.

TO SUBSCRIBERS.

WILL Subscribers please note that only those subscriptions which are sent direct to the Proprietors of THE LANCET at their Offices, 423, Strand, London, W.C., are dealt with by them? Subscriptions paid to London or to local newsagents (with none of whom have the Proprietors any connexion whatever) do not reach THE LANCET Offices, and consequently inquiries concerning missing copies, &c., should be sent to the Agent to whom the subscription is paid, and *not* to THE LANCET Offices.

Subscribers, by sending their subscriptions direct to THE LANCET Offices, will ensure regularity in the despatch of their Journals and an earlier delivery than the majority of Agents are able to effect.

THE COLONIAL AND FOREIGN EDITION (printed on thin paper) is published in time to catch the weekly Friday mails to all parts of the world.

TO COLONIAL AND FOREIGN SUBSCRIBERS.

Subscribers abroad are particularly requested to note the rates of subscriptions given above.

The Manager will be pleased to forward copies direct from the Offices to places abroad at the above rates, whatever be the weight of any of the copies so supplied.

The Milroy Lectures

ON

INFANTILE MORTALITY AND THE RELATIVE PRACTICAL VALUE OF MEASURES DIRECTED TO ITS PREVENTION.

Delivered before the Royal College of Physicians of London

BY S. G. MOORE, M.D. VICT., D.P.H. ENG. CONJ.,

MEDICAL OFFICER OF HEALTH AND LECTURER IN PUBLIC HYGIENE AND SANITATION, TECHNICAL COLLEGE, COUNTY BOROUGH OF HUDDERSFIELD.

LECTURE II.[1]

Delivered on March 14th.

MR. PRESIDENT AND GENTLEMEN,—As already pointed out, it is a matter of course that every statement contained in the official publications of the Local Government Board carries very great authority. Equally as a matter of course one accepts them substantially. But having in mind the fact that it is not given to human beings to be perfect, and fortified by the reflection that I have devoted exceptional attention to this subject for many years, I venture to reiterate the opinion that in these reports too great importance is given to general sanitation in accounting for the reduction in the infant mortality figure observed of recent years, and that too little importance is given to work especially directed to meet the particular circumstances of infant life. In support of this view I exhibit three charts.

INFLUENCE OF SPECIAL MEASURES ON INFANT MORTALITY.

The first (Fig. 1) shows the death-rate in England and Wales and in Huddersfield from 1870 to 1914. It will be observed in the first instance that these two rates follow one another fairly closely, especially of recent years, and that substantially the decline is uniform and progressive. The second chart (Fig. 2), which shows the infant mortality figure in Huddersfield, does not follow the same course, especially in the last nine or ten years. It will be seen that during the period antecedent to 1906 the curve is higher than during the succeeding years. In fact, it is hardly too much to say that the chart can be divided into two periods—one before 1906 and one after that year. It was in 1907 that the special work against infant mortality in Huddersfield came into full operation.

The foregoing considerations are reinforced by the following facts. The city of Liverpool is well known for its efficiency in sanitation, and notably for the attention paid to housing. With the possible exception of Birmingham, no sanitary district has expended so much time and money in this direction. Two years ago the sum of £1,350,000 had been spent on housing schemes, but, as will be seen from Fig. 3, the infant mortality figure remains high. Moreover, it is well known that infant mortality is low in rural and generally in small urban districts, particularly so in agricultural areas, but it is equally well known that sanitation is of the lowest standard in these very places.

I by no means wish to suggest that general sanitation, and especially municipal cleanliness, do not favourably affect the health of infants as of inhabitants generally, but, speaking as one who has given close attention to the problem for a long while, I would lay stress upon the view that other factors are of a greater significance and importance. It is well known that a heavy toll on the lives of the very young is levied in industrial districts where the employment of women is at a minimum, but where the standard of life is low, as well as in other industrial districts where their employment is at a maximum. I believe that the explanation of the former phenomenon is that the infants are individually neglected in the homes of the people, and I have no doubt that a breast-fed baby living in insanitary surroundings, but cared for by its mother would have a very much greater chance of surviving than one bottle-fed and neglected by its mother, however excellent might be the sanitation of the house and the district in which it lived. Instances have been adduced, where in the same street in certain families there have been many surviving children, and in other

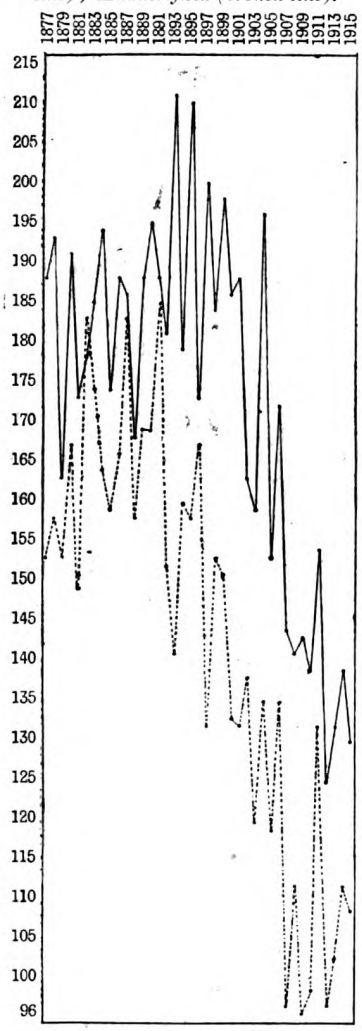
Huddersfield: Infant Mortality since 1877 of Deaths per 1000 Births registered.



[1] Lecture I. was published in THE LANCET of April 22nd, 1916.

families of a similar social grade the survivors have been few. An instance in Liverpool has been cited frequently, where in one house, out of nine children born, all survived, and next door, out of a similar number of births, there was but a single survivor.

FIG. 3.

Infant Mortality: Liverpool (continuous line); Huddersfield (broken line).

In this connexion the fact appears to be worthy of emphasis that if we rely upon improvement in the general sanitation to reduce the excessive fatality among infants, even the most sanguine must recognise that many generations will pass before anything like a satisfactory result can be realised. On the other hand, the events of recent years have demonstrated that special measures directed to individual infants have given results immediate and better than were anticipated.

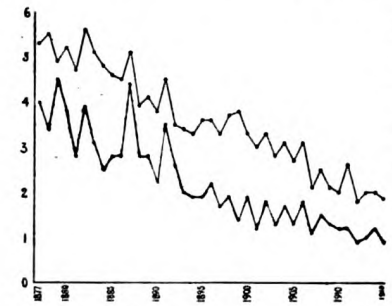
RELATION OF INFANT MORTALITY FIGURE TO RATE IN NEXT FOUR YEARS OF LIFE.

In view of the statements to which prominence has been given to the effect that the result of preserving the lives of infants would have a generally bad effect on succeeding ages, based on the argument that heredity rather than environment should be taken into account, I have prepared the following chart. (Fig. 4.) The curve showing the death-rates per 1000 per annum at ages from 1 to 5 years follows very closely the corresponding curve at age 0 to 1 year. But if the work against infant mortality were only temporary in its influence, the curve at succeeding ages ought to have shown a rise. Of course, this is not the case. I have referred to these arguments against the utility of endeavouring to reduce the infant mortality figure elsewhere and from another point of view. It really does not appear to be worth while to labour the point, but I will recall the fact that in the Local Government Board Reports on this subject the same demonstration is given, and over extended age-periods. The same thing is better seen where triennial periods are taken. By the massing of the figures a smoother curve is obtained. (Fig. 5.)

FIG. 4.

Huddersfield: Death-rate per 1000 per annum—years 1877–1914.

Upper line represents death-rate at ages 0–1 years.
Lower line ,, ,, ,, 1–5 years.



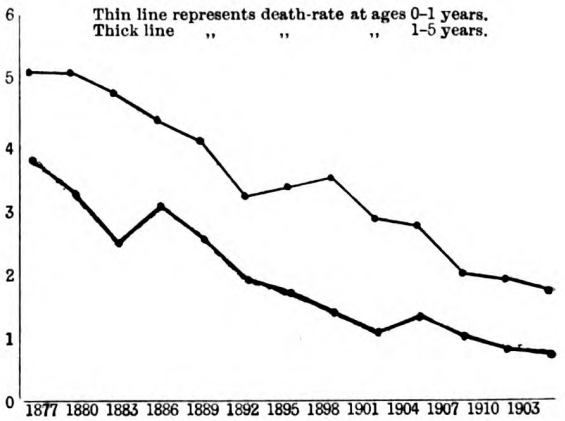


FIG. 5.

Huddersfield: Mean Death-rate per 1000 per annum from 1877–1915 in Triennial Periods.

The result in Huddersfield is amply corroborated by the results shown in the following series of charts giving the death-rates at each of the first five years of life for England and Wales calculated per 1000 survivors at each age-period. (Figs. 6, 7, 8, 9, and 10.) It will be seen that the curves

FIG. 6

England and Wales: Diagram showing the Annual Infant Mortality from 1870 to 1914.

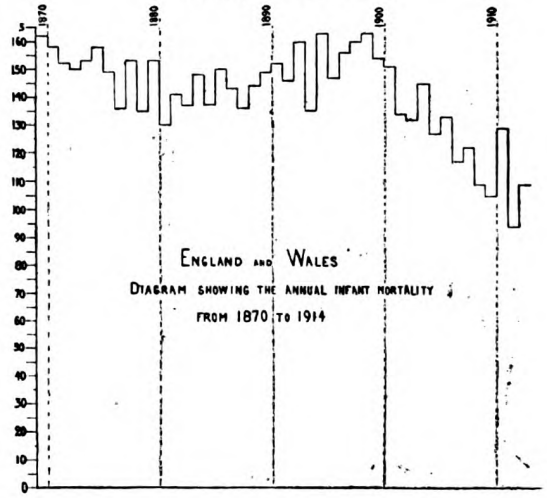

FIG. 7.

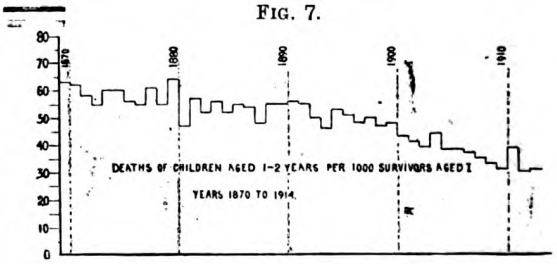

FIG. 8.

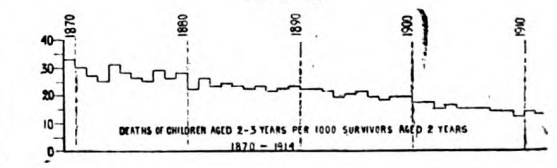

FIG. 9.

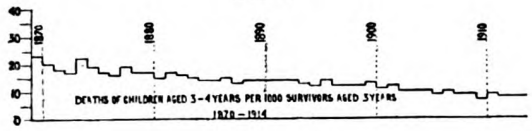

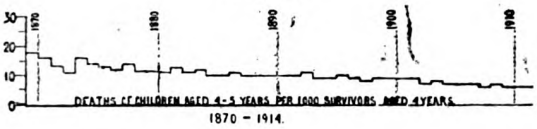

FIG. 10.

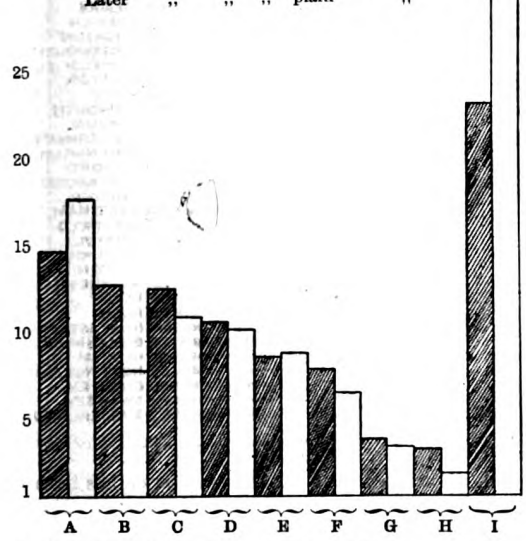


formed, after making allowance for the greater vulnerability at the earliest age-period, substantially follow one another—that is to say, a reduction in the infant mortality rate (deaths under one year of age) is followed by a reduction in the mortality in succeeding years.

PRINCIPAL CAUSES OF INFANT MORTALITY IN HUDDERSFIELD.

These are expressed as percentages of the whole: contrasting 1899–1906 with 1907–1914. This diagram (Fig. 11) is of considerable interest generally and brings out a particular fact of much importance. It displays the diseases which are chiefly responsible for infant deaths expressed as percentages of the total mortality. Those comprised in the "other diseases," represented in the last two columns, have been omitted from individual display for various reasons, principally because each represents so few

FIG. 11.

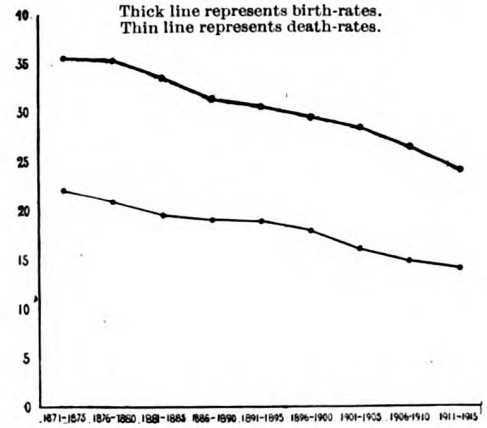
Huddersfield: The principal causes of Infant Mortality expressed as percentages of the whole: contrasting 1899–1906 with 1907–1914.

A, Premature birth. B, Atrophy, debility, and marasmus. C, Diarrhœa. D, Bronchitis. E, Pneumonia. F, Convulsions. G, Whooping-cough. H, Measles. I. All other diseases.

deaths, but also for causes connected with death certification. "All other diseases" caused 23·3 per cent. of the deaths in the earlier period; the sum of the values of the other columns represents the balance 76·7 per cent. The figures for the later period are 30·2 per cent. and 69·8 per cent. respectively.

Apparently the attempt to save infant life in Huddersfield has led to a relative increase of deaths from premature birth, pneumonia, and "all other diseases," and to a relative decrease in all the other principal causes of death—notably from "atrophy, debility, and marasmus," and diarrhœa.

In reflecting on this diagram it should be borne in mind that during the later period, 1907–1914, there was a *positive* reduction of infant fatality and that the diagram displays the transference of the death incidence from one cause to another—hence its significance. And hence the outstanding significance and importance of the fact shown in the first two columns. The proportion of deaths from premature birth rose from 14·9 per cent. to 17·8 per cent. This is compatible with the belief that preventable deaths have been eliminated in part, thus increasing the proportion of deaths which hitherto have been considered to be unavoidable. This belief is strengthened by a consideration of the other columns. Diarrhœa, bronchitis, convulsions, whooping-cough, and measles, in fact, all the columns except that representing pneumonia, show a decline.



Now I am able to state as the result of an extended intimate experience that many persons, including coroners and medical men as well as certain eugenists, hold the opinion that many deaths at early ages result from a lack of vitality consequent on premature birth. If that view be well founded, it appears to follow that atrophy, debility, and marasmus should show a relative increase, coincident with the increase in deaths from premature birth. But the converse appears. In fact, the decrease of mortality from these three factors of the infant death-rate is greatest of all—from 13 per cent. to 8 per cent. of the total deaths. Therefore I feel justified in holding the belief that hygienic procedures directed to counteract the disability resulting from a premature entrance into the world are not, as it were, beating themselves in vain against an inherent ineradicable lack of vitality, but that, on the contrary, they do meet with a not inconsiderable measure of success.

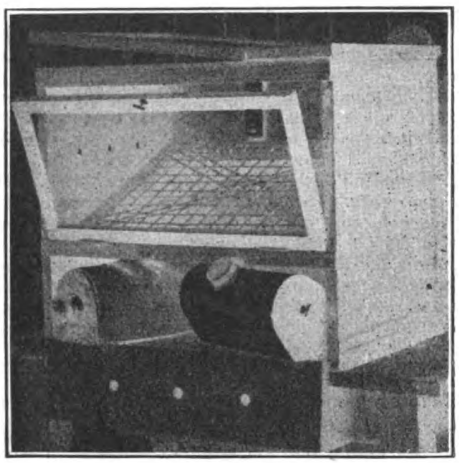
RELATION BETWEEN BIRTH-RATE AND DEATH-RATE IN ENGLAND AND WALES.

It will be seen from Fig. 12 that while both curves are falling, that representing the birth-rate is falling more rapidly than that of the death-rate. As a matter of fact, the reduction in the birth-rate amounts to 32·7 per cent., while the reduction in the death-rate during the period shown is

FIG. 12.

England and Wales: Birth-rates and Death-rates 1871–1915 in Quinquenniads.

36·8 per cent., but the birth-rate has fallen about 12 per 1000 and the death-rate only 8 per 1000. Were individual years shown, of course the curve would not be so smooth. This was seen in the chart showing the death-rates for England and Wales and Huddersfield, which was exhibited in connexion with the fall in the infant mortality figure.



In the present chart the fixed points represent the average death-rate during a period of five years. It will be noted that during the first five-yearly period, from 1871 to 1875, the birth-rate was 35·5 per 1000 and the death-rate 22 per 1000. The fall is fairly uniform for both curves, but that showing the birth-rate is the steeper, so that they tend to run together. At what period this result (which will be calamitous to the race) will be realised we may not attempt to predict; it is probable that disturbing factors will make themselves felt, but it may not be lost sight of that whereas there is nothing to prevent the continuance in the decline of

the birth-rate which may even be accelerated, human vitality does fix a point below which the death-rate cannot fall.

HANDY INFANT INCUBATOR.

Some years ago I was shown in Finsbury a simple form of incubator, suitable for use in the homes of the people, and calling for the minimum of skilled attention. (Fig. 13.) It was made from one of Tate's sugar cases, and divided horizontally into two compartments by means of webbing. In the lower compartment are placed one, two, or three ordinary earthenware hot-water bottles. The infant is placed in the

FIG. 13.

An incubator made from a sugar case.

upper compartment, in which there is a thermometer. The top and sides of the incubator are hinged and glazed. Ventilation is secured by augur holes, some of which are covered by slides, so that they may be opened or closed, and so the temperature may be regulated.

The incubators weigh but little, and can readily be carried about. The total cost is less than 10*s*., but the same thing in a more ornamental form has been placed on the market by a firm of wholesale druggists, Messrs. Sumner, of Liverpool. It will be seen that the manipulation of these incubators is quite simple, that there is no danger of overheating; in fact, they are suitable for use in the homes of the people. At Huddersfield we commenced with two, and have found it necessary to increase the number to six.

In the majority of cases they are used intelligently, and undoubtedly have been of service, but the regrettable fact must be recorded that from time to time the offer of one on loan, without charge, is rejected; and also, from time to time, it is found that after they have been employed for a few days the trouble of tending them seems too great to those in charge of the infant. The same tendency is evinced in another direction; many mothers, rather than be at the pains of tending their offspring in the incubator during the night will take it into bed. There seems some excuse for this. Such mothers argue that the warmth of their own bodies is sufficient and natural.

Records exist of the loan of these incubators on 75 occasions during the last four years. In respect of 16 it could not be established whether or not they were actually used; of the remaining 59, the records showed that they were employed in 32 instances, and that they were not employed in 27 instances. In the former series 21 of the infants lived and 11 died, and in the latter 12 lived and 15 died. Thus, where the incubators were used 65·6 per cent. of the children lived and 34·4 per cent. died; but where they were not used only 44·4 per cent. lived, while 55·5 per cent. died. It will be understood, of course, that the incubators are only used where the infant is very premature and weighs very much below the normal.

The total numbers are so small that if the differences were inconsiderable these figures would be of little value, but when it is recognised that when the appliance was employed almost twice as many premature babies lived as died, and that a greater number died than lived when it was not employed, there can be no doubt that this very simple contrivance has done useful service. But there is another and a dark side of the picture. In a town of 110,000 population, during a period of four years, it was judged desirable by a competent medical authority to provide an incubator with a view of saving the life of a human being on 75 occasions, but those whose plain duty it was to take every possible means, not only to safeguard and to nurture, but to cherish the helpless being, in 27 instances, for one reason or another, did not avail themselves of the help not only proffered but urged upon them.

No excellence of sanitation nor adequacy of municipal cleanliness can by any possibility have affected these particular results, yet to my mind there is an imperative necessity that something be done in this regard, and to me it is clear that action can only follow one or other of two lines—public opinion must be educated, or the State must take action and require protection for such cases. The laws of a country are little more than the codified public opinion, based on the current morals, manners, and customs of the people. But the enactment of a statute would go a long way to cultivate a sound public opinion.

REDUCTION OF INFANT MORTALITY IN LARGE TOWNS.

This slide (Fig. 14) shows the amount of reduction of the infant mortality figure which has been observed in 30 of the large towns of England and Wales, comparing the period from 1877 to 1906 with the period 1907–1914. The reason for the separation of the total period 1877 to 1914 into these two particular parts has been seen in the preceding diagrams which displayed for England and Wales, for Liverpool and for Huddersfield, a definite separation of the curves at that period—one of high infant mortality and another of comparatively low infant mortality.

I submit that this diagram, taken in conjunction with those just referred to, establishes two facts. First, that the reduction of mortality and the saving of infant life has been very substantial, and in the second place, that it has not been

FIG. 14.

Infant Mortality (30 Large Towns).

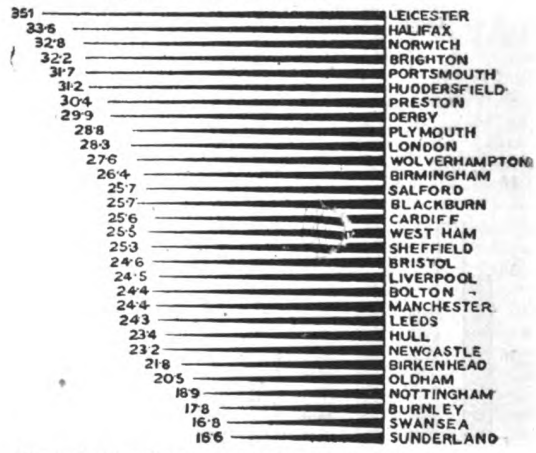


Chart showing the improvement per cent. in the two means 1877–1906 and 1907–1915.

gradual. But the improvement in sanitation has been slow, gradual, and not marked by any abrupt change. The same is true of municipal cleanliness, the spread of education, the habits of the people, and so on and so forth. The facts displayed here constitute one of the reasons which led me to the conclusion that it is by direct rather than by general methods that we must hope still further to improve the babies' chances of surviving.

EXPECTATION OF LIFE IN HUDDERSFIELD.

One result of universal compulsory elementary education has been an enormous increase of printing and, it follows, an enormous amount of reading. We recognise that some printed matter stimulates thought, but that can hardly be said of the reading printed day by day in the press; at least, I do not think that it leads to excogitation on the part of the masses. Many absorb the printed word and rest content at that, instead of pondering the matter and resolving for themselves the ultimate significance of the facts stated. Thus we

read and speak of the reduction which has taken place in the deaths among babies, and in a general way we accept this as being a good and desirable thing. We become vaguely conscious of some of the consequences in increased health, diminished sickness, and reduced mortality.

I wonder how many of those who have considered this subject have asked themselves the question: What is the result on the expectation of life of this reduced infant mortality, and ought not the insurance companies to reduce their premiums in consequence? I cannot (at least I will not) answer the latter part of the question at all, neither can I state the increased expectation of life at birth for the whole country; but owing to the kindness of Mr. Moorhouse, the actuary to the Friends' Provident Institution, I am able to do this for Huddersfield, both for males and females:—

	Assumed deaths during first year per 1000 births.	Complete expectation of life; years.	
Males	156	49·4	+ 3 years net.
... ...	105	52·4	
Females ...	156	51·8	+ 3·1 years net.
... ...	105	54·9	

The mean infant mortality figure prior to the special work against infant mortality in Huddersfield was 156. The mean since that work has been in operation is 105. Thus this particular work has added three years to the life of each generation.

EXISTING PROVISIONS FOR INFANT AND CHILD WELFARE.

As a preliminary to a consideration of the relative value of measures directed to the protection of infant lives, it will be well if we try to take stock of what is being done at present, and here we meet with a difficulty which presents the problem in a new phase. I think I may state that it is manifest that the work of protecting the young human being ought to be done naturally, as a matter of course, and ought to be done adequately by the parents and by the State. Furthermore, that provision ought to be made in the statutes governing the Realm to ensure the same. How strange, how singular, is it not, that the existing state of affairs has *quite recently* been discovered to be such that special and extraordinary measures have been found to be necessary, and have come into being? Yet that even to-day the laws under which we live do not take these things into cognisance. Apart from the Children Act, I think I am safe in stating that while the legal rights of infants to property are safeguarded, our statutes contain nothing, unless it be some archaic and forgotten medieval law, which in any way protects the natural and primal right of the infant. It will be, of course, understood that I do not refer to the ordinary laws (in whose protection we all share) against assault, murder, and that sort of thing.

Well, what are the works which have come into being of recent years? Provision is made, more or less systematically, and more or less completely, for notice to be taken by the sanitary authority of the existence of the infant. As we have seen, less than ten years ago this was done for the first time in Huddersfield, and only last year did it come into operation for the whole country (the significance of the fact that the number of deaths of infants which occurred under the old system was excessive may not be lost sight of). This is followed, more or less completely, and more or less systematically, by a visit to the infant in its home, and here let it be recognised that the quality of the service rendered is very unequal and leaves much to be desired. I will have more to say on this point later.

Next we have health societies. The Directory of Health Societies, compiled and issued by the National League for Physical Education and Improvement, contains the names of 489 different associations. Nine of these are national, 70 are municipal in the sense that they are associated with, and assisted by, different sanitary authorities; the balance, 410, are purely voluntary. As a result of a scrutiny of the annual reports issued by these societies and a computation based thereon I estimate that they assist annually 155,000 infants. It will be understood that this is by no means an actual number; the estimate is very rough and ready, for more than one reason—e.g., when we find that one society states that 500 children made 900 attendances, another society with 300 children have 2350 attendances, and a society with 100 children had 1550 attendances, one is driven to the conclusion, even after making allowances for different procedures, that the figures may not be accepted as being rigidly accurate. Another reason is that the figures are based on a small number out of the total.

The activities of the different societies do not appear to bear any very definite relationship with the titles under which they function. The work which they undertake is very varied. Thus, they visit in the homes, either by means of paid or voluntary assistance; they maintain institutions to which infants may be brought. In some of these, only hygienic advice is given; in others, treatment is also afforded. Others give lectures on a great diversity of subjects. Others, again, hold classes where practical work bearing on the welfare of infants and children is demonstrated. Very many issue leaflets containing advice. A few day nurseries are maintained by voluntary societies, and many provide clothing for the infants and food for the mother or infant. In addition to the foregoing, in six localities antenatal work of various kinds has been established. This side of the work is still very recent and undeveloped; no doubt very much more will be done in the near future.

This summarised statement is all that the occasion permits, but I trust it will lead to a recognition of the fact that a large amount of very excellent work has been organised and is being carried out in this country by ladies and gentlemen who are actuated by a sincere desire to serve their fellow men, and who do render this service at the cost of much time and labour to themselves. Conduct of this kind deserves commendation and obtains our sincere admiration. Yet it partakes of the nature of charity. The infant has the right to protection.

Next we have milk depôts, the English form of "gouttes de lait." Here let me say in passing that I trust there will not arise in England anything at all resembling the unfortunate rivalry which arose between Variot and Budin in Paris—the one maintaining the excellence and desirability of the "gouttes de lait" against the other who advocated the consultations. To the onlooker it was manifest that both organisations were doing excellent work. These milk depôts are places where milk is modified and pasteurised and placed in a number of bottles sufficient for the daily supply, so that each contains one meal for the infant, the idea being to provide an appropriate and safe food at each age. They had a great vogue some years ago, especially in France and Spain. (In the United States a prominent citizen of New York, Mr. Nathan Strauss, whose wealth enabled him to operate on a scale commensurate with the size of the city, distributed annually more than one million bottles and more than three million glasses of pasteurised milk. He has published interesting reports, which show clearly that the result has been highly beneficial.) In this country 13 such institutions have been established, 5 of which are in London. This movement against infant mortality, however, appears to have languished. Eleven were opened between 1899 and 1906, one in 1910, and one in 1912. Four have been closed. The cost in relation to the number of infants helped appears to be the stumbling block. There can be no doubt that the cost per meal of pasteurised milk is considerable. On the other hand, it is surely an imperative thing to provide food for infants which will not destroy them. Yet such are the conditions of the industrial milk-supply in this country that in hot weather the only milk commercially available for poor people does, in fact, destroy babies in large numbers. Of this there is ample evidence.

The "infancy" of the whole movement for the protection of infants is well demonstrated by the fact that it is only within the last two or three years that the Government has become awake to the need for considering the health and safety of the unborn child. But to-day work is being undertaken in this direction. Apart from a few isolated infants' hospitals (I think I am safe in stating that the total in the British Isles could be numbered on the fingers of one hand), in addition it may be to maternity wards in workhouse infirmaries, this completes the list of measures available for the prevention of infant mortality and the protection of infant life in this country at present.

INFANTS' FOODS.

I do not recollect finding in the reports of the Local Government Board on Infant Mortality any special reference to the artificial (so-called "patent") babies' foods, many of which used to be, and some of which are still, largely advertised. Neither is there any reference to anything of the kind in the Villiers-le-Duc report. Apparently in the

latter case the need did not arise. Here, again, we have an example of the singular apathy of the "powers that be" with regard to the interests of the infant. It is, of course, a simple and well-known fact in physiology that until the age of five months an infant is unable to digest starches. One would have supposed that it would have been a very serious offence for any person for the sake of profit to attempt to place starch on the market and call it babies' food. One would suppose that there was no special need for advocacy on this point, but it is the case that to-day there is nothing to prevent such action on the part of any person, and this in face of the fact that serious formal representations have been made unavailingly to the Government department concerned, with a view to preventing this abuse, or rather this crime.

Surely it is not too much to ask that an infant be not slowly starved to death by having administered to it a substance which does not nourish it. The mind reels before a contemplation of the number of infants who have been slowly done to death in this horrible fashion in this country during the past 50 years. No words can be too strong in condemnation of the system which permits the interests of commerce to stand in the way of the utter, ruthless uprooting—the total obliteration of this system.

ON THE TREATMENT OF GUNSHOT FRACTURES:

A DESCRIPTION OF APPARATUS AND TECHNIQUE.

BY ERNEST W. HEY GROVES, M.S. LOND., F.R.C.S. ENG.,
MAJOR, ROYAL ARMY MEDICAL CORPS;
AND
THOMAS H. BROWN, M.B., B.C. CANTAB.,
CAPTAIN, ROYAL ARMY MEDICAL CORPS.

INTRODUCTION.

IN a typical gunshot fracture there are three main characteristics: great comminution with displacement, severe sepsis, and pain which becomes intolerable with movement. A patient with such a fracture is in great danger of losing either life or limb from sepsis or hæmorrhage, and if he escapes these early dangers, recovery of the limb is generally a matter of months, and, unless special precautions are taken, will leave him with a deformed and almost useless member.

Any system of treatment of such fractures must aim at saving both life and limb, and restoring the latter to useful function. In order to do this four things are necessary: (1) Immobilisation of the fractured part for a prolonged period; (2) thorough treatment of the wound, by free drainage and frequent dressings; (3) restoration of the correct line and length to the bone by extension in its axis; (4) maintenance of both wound treatment and extension for a period which may be prolonged to several months. And as accessories to the above two further conditions are desirable: (5) The joints being kept semiflexed, so that the limb is in physiological rest, and the flexor muscles relaxed; (6) massage and movement of the limb from an early period.

The Treatment of Grossly Infected Wounds.

Shell and bomb wounds which are obviously grossly infected should be opened up freely at the earliest possible moment. It is not justifiable to leave such for X ray examination, if this is not immediately available. Large pieces of shell and scraps of clothing can readily be extracted by enlargement of the wound, and it is much more important to do this at once than to wait for radiographic information. For this type of wound there is safety only in *opening early* and *opening freely*. Small punctured and penetrating wounds without evidence of infection are better left alone with a simple dressing until admission into a base hospital.

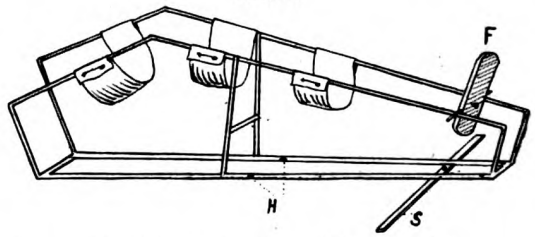
Treatment of Fragments in a Comminuted Fracture.

However freely the wound is opened up the bone fragments must be left *in situ*. However much the bone is comminuted the fragments are seldom bereft of all vascular supply, and when the wound becomes healthy they will re-form the broken parts. It is only too easy to remove several inches of the shaft of the bone if every movable fragment is seized which can be felt in the wound. Then the limb will be left in a useless condition and, apart from a late grafting operation, nothing can be done to restore it. There are only two exceptions to this rule of not removing fragments of bone: first, when the articular end of a bone is shattered, all loose bone should be removed from the joint; and, second, if a bit of bone is clearly devoid of all vascular connexion and lies in a septic wound it should be taken out.

The Avoidance of Operative Fixation of the Fragments.

It is useless and very dangerous to attempt to plate or wire bone fragments lying in septic wounds. If much comminution exists this will be a mechanical impossibility and if the fracture is not comminuted it is excellently suited for extension treatment. Boring holes in a bone in an infected wound will usually lead to necrosis of that portion of the bone which is fixed by a plate, and though for the moment the patient may be better for the immobilisation he will run a grave risk of losing the limb later.

It is necessary to preface the description of the splints and extension apparatus by these remarks because they involve cardinal principles. Unless a grossly infected wound is opened and drained early and thoroughly, unless the fragments of bone are left in place, and unless unnecessary operative fixation is avoided, no subsequent splint or apparatus will serve to save a useful limb, nor, indeed, will it save the limb or even the life in many cases.



FRACTURES OF THE FEMUR.

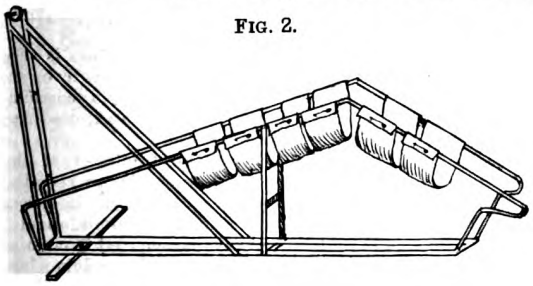
1. *In the Early Stages.*

At the clearing station the limb should be put up on the wire-cradle leg-splint, and in all the stages of transport it is to be left on this splint. This is very easy of application, because it merely requires the leg with flexed knee to be laid in it. No bandaging is necessary, except round the foot and leg below the knee when the patient has to be transported. It is comfortable for transport, because the flexed position of the joints prevents all rolling, and there is a cross strut which takes a bearing on the stretcher poles.

The wire-cradle leg-splint, short pattern (Fig. 1).—This consists of a wire frame, fixed on a metal base, with a cross-piece at the lower end, the long end of which is turned towards the sound leg. It is to be used for any fracture of

FIG. 1.

Wire cradle-splint; short pattern. Only three strips are shown, and about four more would be required; F, Foot-piece; H, Holes for fixing extension uprights; S, Cross strut which can be turned with its long end either side.



the lower two-thirds of the femur or of the leg below the knee. It is prepared for use by placing slings of rubber or of flannel bandage across from side to side for the whole length of the leg. These slings should be of such a length as to allow the leg to lie with its upper surface on a level with the splint. Rubber slings are used opposite any part which is wounded, and also below the knee. In the former case this is for cleanliness and in the latter to afford an elastic extension of the thigh. The knee is flexed over the elastic band and this will pull upwards away from the hip; this extension sling therefore should be adjusted fairly tightly and covered with a generous pad of wool. The rest of the slings are made of double slips of flannel bandage, secured by safety-pins.

When the splint has been converted into a cradle by the adjustment of the rubber and flannel slings, it is applied simply by raising the leg, keeping traction on the thigh and bending the knee and placing the limb upon the splint, so that the knee lies at the bend of the wire frame. The tension of the slings is then adjusted so that even support is obtained along the whole leg. If the patient has to be moved or is delirious, the foot and leg are bandaged to the splint, but otherwise this is not necessary, because the cradle in which the limb lies, being a double inclined plane, does

not allow of the limb moving from its position. When the wound is dressed the rubber slings are unfastened from the outer bar of the frame and dropped out of the way. Anterior wounds do not require the slings to be moved at all and a posterior wound can be so treated that a sling lies above and below it, so as not to imprison discharges or block the mouth of a drainage-tube.

The wire-cradle leg-splint, long pattern (Fig. 2).—This is exactly like the short pattern in principle, but it is longer. One bar of the wire frame is longer than the other in order to take the longer, outer side of the thigh, and the frame is so bent back at its upper end as to allow the bedpan to be slipped underneath it.

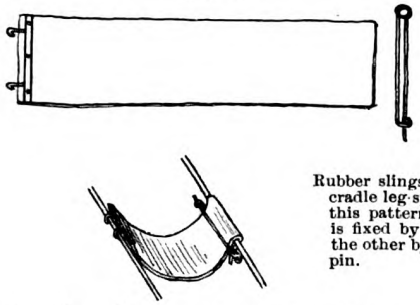


FIG. 2.

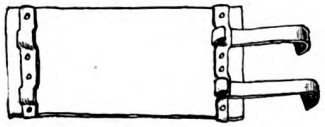
Wire-cradle leg-splint; long pattern. The extension uprights are detachable. In a more recent pattern both side bars of this splint are of the same length but they are supported at a higher level, so that the inner one clears the pubes. By this modification the same splint will suit a right or left leg.

The use of rubber slings.—The rubber slings may be made of ordinary rubber bandage, used in double thickness and fastened by a safety-pin. But for the support of the leg it is much better to use the stout rubber, which can be obtained by cutting up unserviceable motor-tyre inner tubes. The disused tyres can be obtained from any ordnance stores.

FIG. 3.



Rubber slings for wire-cradle leg-splints. In this pattern, one end is fixed by hooks and the other by a brooch-pin.

The thick rubber sling may be fixed to the wire frame by turning over each end round the wire and clipping by a brooch-pin made from steel wire, or by hooks made from the ribbon aluminium used in the field fracture cases. Different methods of attachment are shown in Figs. 3 and 4.

2. *In the Later Stages.*

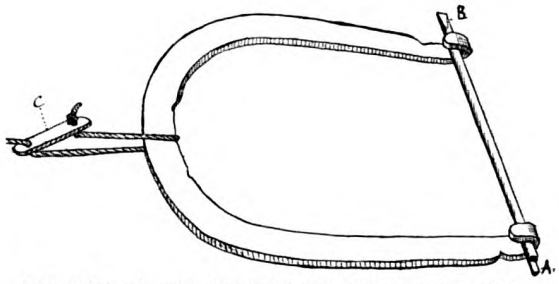
The treatment above described is all that is necessary for the early stages—i.e., for a week or ten days—but when the patient has arrived at a base hospital a more exact and efficient extension is necessary in order to secure the correct length and alignment of the broken femur. The patient is first examined by the X rays. This is done while he lies on the splint, the only alteration necessary being that for the moment the rubber slings near the fracture should be replaced by flannel. Extension is attached to the limb either by means of adhesive plaster or by a transfixion pin. In either case it will be necessary to fix the two metal uprights and pulley wheel to the splint by means of four bolts. The pulley wheel can be adjusted at three different heights in the uprights. (See Fig. 2.)

FIG. 4.

Rubber sling fixed and adjusted by slips of aluminium ribbon which can be bent and cut to any length; these are only shown here at one end of the sling.

Extension by plaster.—The ankle and heel are protected by a layer of wool and a bandage, the leg is shaved and washed with spirit. Zinc oxide adhesive plaster is then fixed to a wooden spreader and attached to the leg as high above the knee as the wound will allow. Circular strips of plaster surround the limb from the ankle to the tubercle of the tibia (the crest of the tibia being protected from pressure by a strip of gauze), and from the upper border of the patella to within a safe margin of the wound. A bandage surrounds the plaster. A cord is taken from the spreader to the pulley placed in the middle hole in the uprights and a 20 lb. weight attached. In this method the slings which support the thigh and knee must be lowered and those under the calf raised, so as to keep the knee almost straight. The foot is supported by the weight in mid-air.

It will often occur that the plaster loosens or slips; this is due to the shrinking of the limb owing to subsidence of inflammatory swelling and to emaciation. In this case it is necessary to re-apply it or to replace it by transfixion. This method is perhaps the best in the early stages of very septic cases. Not only does it avoid transfixion at the stage of infection, but it tides over the first period of treatment and allows transfixion to be postponed until the time when bone union is taking place. It is liable to cause soreness unless very carefully applied, and the direct pull on the almost straight knee is a great disadvantage.



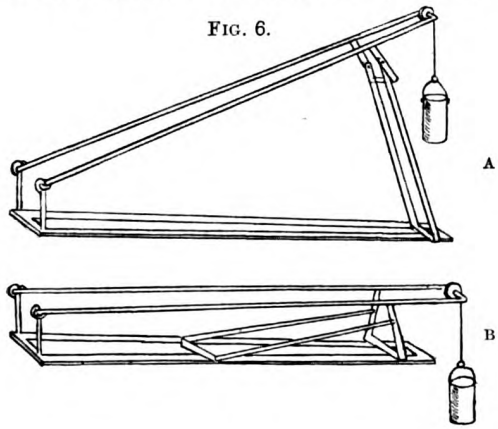
Counter extension.—However extension is applied, counter extension is necessary from the outset, otherwise the patient is pulled down and the splint and the adjustment is disturbed. Counter extension is provided by a well-padded flannel bandage round the sound thigh tied to the head of the bed, and also by raising the foot of the bed on 8-inch blocks.

Transfixion extension.—When the wound has assumed a healthy character it is usually more satisfactory to apply extension by means of a transfixion pin passed through the condyles of the femur or the head of the tibia.

It is wise to use the tibial site of transfixion for all cases in which the fracture is near the knee-joint, and also in those in which there is reason to anticipate a slow progress of union. There is not only less liability to septic ulceration round the pin-holes, but if this does occur it does comparatively little harm, whereas at the lower end of the thigh there is danger of sepsis spreading from the pin-holes into the muscular planes of the thigh or even into the knee-joint.

On the other hand, the femoral site of transfixion has the advantages of pulling directly on the lower fragment and of not interfering with passive movements of the knee during treatment. Transfixion is performed by a plain steel pin $6\frac{1}{2}$ inches long and 3/16th inch thick, with a sharp chisel point at one end and a slot which fits a hand brace at the other. (Fig. 5.) The leg lies in its cradle-splint to which the extension uprights have been bolted and the pulley wheel fixed at the highest position. The lower end of the thigh or the upper end of the tibial region is painted with iodine and the patient is given gas in bed. An assistant stands on the outer side of the patient and steadies the limb, and pulls the skin upwards towards the fracture. The surgeon drives the pin into the limb either at the upper part of the internal condyle or into the inner tuberosity of the tibia just above the level of the tubercle. The pin cuts its own way into the skin and through the outer shell of bone propelled by a firm jerk, and then the pin is driven through the bone by rotation of the brace and cuts its way out of the skin on the farther side. In this way the holes made in the

FIG. 5.



Transfixion pin with horse-shoe claw and extension cord; A, Slotted end of pin to fit brace; B, Chisel point of pin; C, Tightening stay.

skin by the pin are just large enough to take the pin and leave no open wounds. The spots of entry and exit are covered with pads of dry gauze and a bandage. The projecting ends of the pin are grasped by a metal horseshoe, by which a cord is fixed over the pulley to a weight of 15 lb. (Fig. 5.) The transfixion pin is left in place for a period of from four to eight weeks. The shorter time is usually sufficient when the fracture is in the lower third of the femur and in the absence of retarding suppuration. The longer period may be used in tibial transfixion. If firm union has not occurred at the end of six weeks in the femoral transfixion or after eight weeks of tibial, adhesive plaster may be applied for a further period after its removal, but this is not often necessary. The progress of union may be judged both by the X rays and the absence of pain at the site of the fracture on removal of the weight.

Massage and movements.—In the majority of cases, and all in which the wound is doing well, the whole of the limb apart from the wounded area is massaged from the end of the first week until the patient is able to walk; from the end of the second week the knee-joint is moved gently once a day from extreme extension to a flexion of 45 degrees and the ankle has all its movements imparted to it.

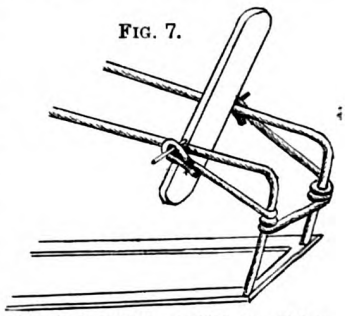
The hinged wire-cradle leg-splint.—There is one objection to the elevated position of the thigh in the treatment of septic fractures of the femur. In some cases the suppuration tends to track towards the hip. This is usually the result of the wound not having been thoroughly opened or of proper drainage not having been provided. If this tendency is observed and cannot be checked by proper drainage, the case should be treated by a hinged splint which, whilst keeping the limb horizontal, allows of it being elevated for dressing without disturbing the extension. This hinged splint (Fig. 6) consists of a stout wire frame which lies on each side

FIG. 6.

Hinged leg-splint; A, Raised position for dressing; B, Horizontal position to avoid upward tracking. In a more recent model of this splint there are two improvements. The upper ends are supported on curved instead of straight uprights, the curve being a quadrant with a 6-inch radius. This serves to allow clearance for the bed-pan. The lower end of the movable frame is bent upwards and there are two pulley wheels, the upper one to take the pull direct from the femur and the lower one to take a pull by adhesive plaster through the leg and foot.

of the leg, hinged to a metal base. The frame-work carries a pulley-wheel on the cross-piece below the foot. A swinging strut serves to support the frame when the latter is elevated to 45 degrees. In order to apply this splint, either adhesive plaster or a transfixion pin is necessary for the attachment of extension. If a pin is used, then instead of a horse-shoe attachment between the cord and the pin, two cords are brought down each side of the leg from the ends of the pin and fixed to a cross-piece of wood or metal which lies below the sole of the foot, and to which the weight is attached by a third cord. If adhesive plaster is used then a foot-piece (see below) is used as a spreader and the weight is attached to this. When an attachment for the weight has been provided by one of these means the splint is converted into a sling in the same way as the other pattern by the use of flannel or rubber strips, these being adjusted so as to allow the back of the thigh to rest at the level of the bed. The limb is placed in the cradle thus made for it, the upper or hinged ends being placed as high as the perineum will allow, the inner end being protected by padding; counter extension is provided, as before, by a perineal band round the sound thigh. When the dressing is done the frame cradle is raised to an angle of 45 degrees and the strut swings into place. Then the whole of the back of the thigh is accessible when the slings are removed, the tension of the weight serving to keep the bones in position.

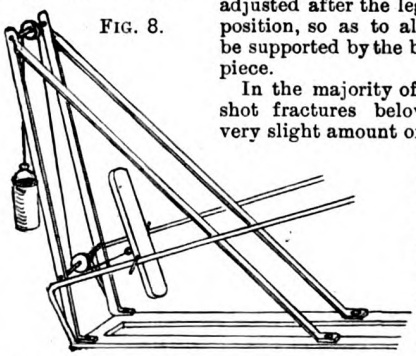
It might be thought that the purpose of this splint would be equally well served by simply keeping the limb lying on the bed with a weight over a pulley at the lower end, but when such a limb is lifted without mechanical aid it is found quite impossible to hold it at a sufficient elevation and without varying the tension, and the cardinal principle of immobilisation is violated daily.



I have found in many bad cases where suppuration is very slow in clearing up that it is very convenient to begin by six weeks' transfixion extension on a double inclined plane cradle-splint, and then to attach adhesive plaster and continue with the hinged splint until union is complete.

On the necessity for abduction.—In all fractures of the upper part of the femur it is absolutely essential to keep the thigh abducted, because otherwise adduction of the lower fragment will be brought about with consequent angular deformity. This abduction will always be secured if counter extension is made from the sound side of the pelvis while extension is maintained on the injured leg. It is necessary to point this out, because both the patients and nurses are liable to leave off the perineal counter extension, and if the elevation of the bed alone is used to prevent the weight pulling the patient down, abduction is not secured.

FRACTURES OF THE TIBIA AND FIBULA.



If there is much comminution with large discharging wounds, it is just as necessary to elevate the leg from the bed as in fractures of the thigh. The short pattern leg cradle-splint above described and figured is to be used. (Fig. 1.) Above the knee in the thigh portion one or two stout rubber slings are placed. The lower end of the thigh is protected from pressure on the hamstring tendons by suitable padding. These rubber slings serve as an elastic counter extension. A foot-piece with a cross metal bar which slides on the frame is fixed to the leg. This is done preferably by adhesive plaster running up the sides of the leg, the ankle and heel being properly protected by wool and bandage. But if the wound is too low down for this, then the foot-piece must be bandaged on to the foot by a starch bandage, the dorsum of the foot being well protected by padding. The leg part of the splint is provided with slings, either of rubber or flannel, the length of these being adjusted after the leg is placed into position, so as to allow the foot to be supported by the bars of the foot-piece.

FIG. 7.

Elastic extension, applied by rubber tube to the foot-piece.

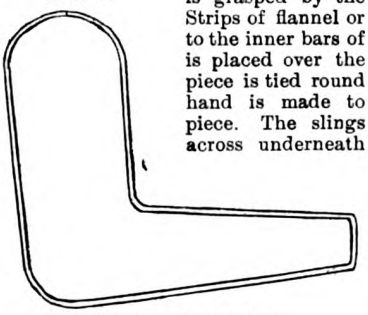
FIG. 8.

Weight extension, applied to the foot-piece. In a more recent pattern of the short leg cradle splint there is provided a slot at the lower end into which a cross rod bearing a pulley can be fitted. This provides for weight extension without necessitating the special uprights.

In the majority of cases of gunshot fractures below the knee a very slight amount of extension will prevent or correct overlapping of the bones if the limb is kept in this position, which, by reason of the flexion of the knee and the extension of the ankle, relaxes the calf muscles. This extension is brought about by a piece of rubber tubing half an inch thick and about 12 inches long, each end of which is tied into a loop by string binding. The tube is passed across the uprights of the wire

cradle (not the extension uprights, which are not necessary) and wound round these two or three times and the ends looped over the outstanding bars of the foot-piece. (Fig. 7.)

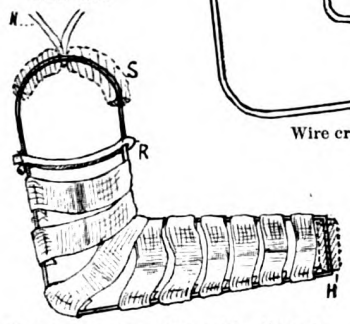
In cases where this extension is not sufficient the extension uprights are fixed to the splint, the pulley placed in the lowest position, and weight applied to the foot-piece. (Fig. 8.)



In cases of some long standing when much overlapping has occurred and certain closed fractures with much muscle spasm, it may be necessary to use some form of transfixion. The best site for this is the malleolar region or the os calcis and the pin 4 inches long and ⅛ inch thick is used. To this a 10 lb. weight is attached, and very soon serves to correct the displacement.

FRACTURES OF THE ARM.

In many arm fractures there is nothing like the same urgency for special apparatus as in the case of the leg, and very often, though the fracture is comminuted, there is very little real displacement or loss of continuity. But if the limb is severely shattered exactly the same principles must be observed, as have been detailed above.



The wire cradle-splint (Figs. 9, 10).—This splint, shaped like a capital letter L, is made of ¼-inch steel wire, rounded at the top where it lies over the shoulder. This part and the small cross-piece at the lower end, which is grasped by the hand, are padded. Strips of flannel or rubber are attached to the inner bars of the splint, and it is placed over the arm. The shoulder-piece is tied round the neck and the hand is made to grasp the hand-piece. The slings are then brought across underneath the arm and pinned to the outer bar. It is often convenient to use a single broad sling for the unwounded part of the limb. For example, if the humerus is fractured the whole forearm may be slung in one sheet of lint and separate rubber slings used for the upper arm. The uppermost strip, which lies in the axilla, is formed of a double drainage-tube which can be lightly padded. In bad cases, when the patient is in bed, the whole limb is slung to a bar at the side of or across the bed, where it can be submitted to constant irrigation.

FIG. 9.

Wire cradle arm-splint.

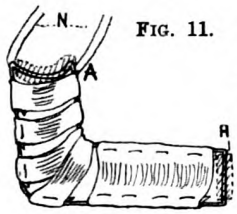


FIG. 10.

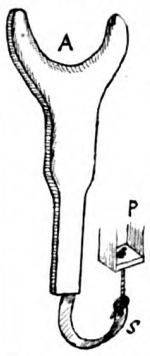
Wire cradle arm-splint with slings in position. N, Bandage round neck; S, Padding over shoulder; H, Padding for hand; R, Rubber under axilla.

The arm-cradle with axillary bar (Fig. 11).—It is sometimes more convenient to have the upper end of the splint in the axilla instead of over the shoulder. The cradle-splint can be given this form by bending the upper rounded part at right angles to the arm-piece; when so bent the splint will form an inside angular splint for one arm or an outside angular splint for the other.

FIG. 11.

Wire cradle arm-splint. Upper end bent into axilla; N, Bandage round neck; A, Padded bar in axilla; H, Pad in the hand.



Extension either of the humerus or forearm can be provided for in this splint as follows. For the humerus, by bending the upper end into the axilla and padding the same, and then passing a rubber bandage across the flexor aspect of the forearm and the outer bar of the lower portion of the splint for several turns.

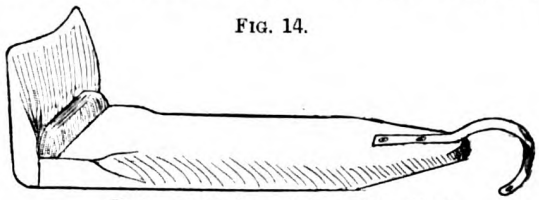
For extension of the forearm the hand must be firmly bandaged to the hand-piece, and the arm drawn back to the outer bar of the splint by a rubber bandage passing across the front of the biceps.

Special Extension Arm-splints.

In those cases where the wounds are less severe and in which much displacement of the bone exists, it is necessary to use some form of constant extension in order to obtain correct length and alignment of the broken bones. This is arranged for in the splints described below by means of a ?-shaped steel spring, capable of keeping up a constant tension of 5 to 8 lb. (when the tip of the spring is displaced one inch towards the shaft there is a tension of 7 lb.).

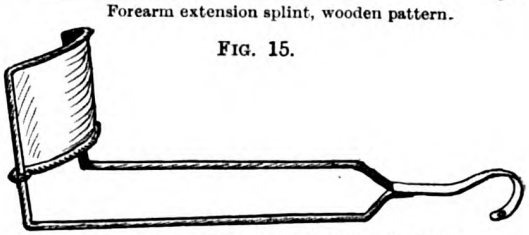
FIG. 12.

Humerus extension splint, wooden pattern; A, Padded crutch for axilla; P, Adhesive plaster attached to arm; S, Spring to give a 5 lb. pull.



The humerus extension splint. — The body of this is made either of wood or metal. It consists of a Y-shaped piece, the upper part of which is well padded and placed in the axilla. (Figs. 12, 13.) Adhesive plaster is fixed to the arm below the wound and to a wooden spreader which lies just below the elbow. From this a cord hangs down. The splint is placed in the axilla and the extension cord is passed through the hole in the spring. The latter is pulled towards the elbow with a tension of 5 lb., and the cord is then tied in this position. No bandage is necessary to keep the splint in position. Every third day the splint is taken off, by merely unknotting the extension cord, and the axilla is rubbed with spirit and dusted with powder.

FIG. 13.



Humerus extension splint, metal adjustable pattern.

FIG. 14.

Forearm extension splint, wooden pattern.

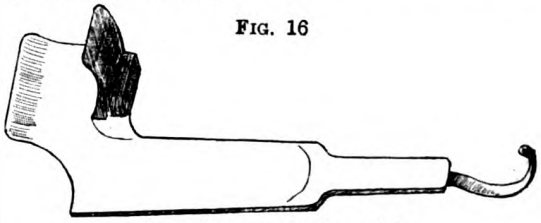


FIG. 15.

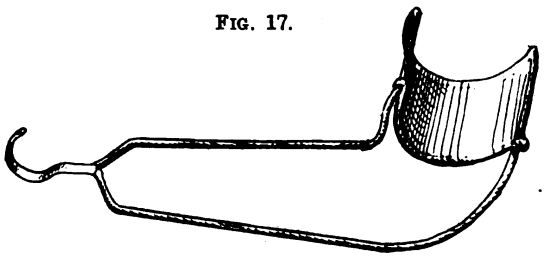
Anterior angular extension splint, metal pattern.

Forearm extension splint (Figs. 14, 15): *Anterior angular pattern.*—This, too, is made either in wood or as a wire frame, shaped like an anterior angular splint bearing the ? spring at its lower end. The metal frame splint is much better than the wood for cases which have large wounds in the forearm, and also because the fingers are not imprisoned against the splint.

FIG. 16

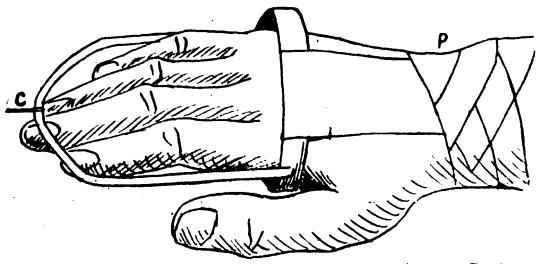


Antero-internal extension splint.

Internal angular forearm splints (Figs. 16, 17).—In some cases, especially where the wound is near the elbow-joint, the

splint is more conveniently arranged as an internal angular pattern, with a piece coming forward in front of the biceps

FIG. 17.



Antero-internal angular extension splint, metal pattern.

for counter extension. This antero-internal angular splint is also made in wood or as a wire frame.

Attachment of adhesive plaster to the forearm.—If adhesive plaster be taken along the flexor and extensor surfaces of the forearm and fingers, the latter being held rigid in full extension become stiff and painful and the flexor muscles are kept in full tension. To avoid this a hand-piece (Fig. 18)

FIG. 18.

Hand-piece for attachment of extension to forearm; C, Cord to be tied to spring; P, Adhesive plaster.

is used for attachment of the strapping. This consists of a flat aluminium band which surrounds the palm of the hand inside the thumb, and to this the extension plaster is fixed. A ∩-shaped wire goes from one side of the flat band to the other crossing the fingers at their lower joints. To this wire the extension cord is tied and the cord is knotted into the hole in the extension spring.

The appliances described in this article are made by Messrs. Down Brothers, London; Messrs. Ferris and Co., Bristol; and Messrs. Young and Co., Edinburgh. They can be obtained also by Royal Army Medical Corps officers from the Central Splint Factory, Alexandria.

SOME PERFORATIONS AT OR NEAR THE PYLORUS.[1]

BY W. H. BATTLE, F.R.C.S. ENG.,
SURGEON TO ST. THOMAS'S HOSPITAL.

THE presence in the wards of a woman who has undergone treatment for perforation of a chronic ulcer near the pylorus provides an opportunity of considering some of the problems presented by such cases. During the past few months the imperative demands of the military side of the hospital have not relieved us of our duty to civilian patients, and several of these abdominal catastrophes have been admitted during that time. The guiding principles in the management of gastric and duodenal perforations are in the main generally recognised, but details must vary according to the time elapsed since perforation, the position and size of the ulcer, the extent of the induration surrounding it, and the amount of contraction following the partial improvement which may have attended nature's unsuccessful attempts at a cure. These statements are more especially true when the ulcer is at or near the pylorus.

In the first case the diagnosis was made and operation performed within two hours of perforation. The operation was done through a planned epigastric incision, which was closed in layers, and has left a firm abdominal wall. No drainage was necessary and recovery was uneventful.

[1] A paper founded upon some clinical lectures delivered at St. Thomas's Hospital.

CASE 1. *Perforation of duodenal ulcer; operation within two hours; no drainage.*—A married woman, aged 26, was admitted to St. Thomas's Hospital on Oct. 26th, 1915, with an attack of acute abdominal pain commencing an hour before. She had not vomited, but the pain had been so severe that she had fainted twice. Indigestion had existed for five years, and three years ago she was in this hospital for two months complaining of pain after food and vomiting. Since then she had been comparatively well until August last, when the same symptoms returned and she had been obliged to take to her bed. As solid food caused much pain she was avoiding it as much as possible, and on the day of admission had only taken milk and soda-water. The pain complained of had commenced suddenly when she was lying down and was lower than usual, in the region of the umbilicus, but was not referred to either side.

The patient, a thin woman, was pale and perspiring, with quick and shallow respirations, temperature 98° F., and pulse 140. The abdomen was very rigid, not markedly distended, and moved very little with respiration. There was great tenderness in the epigastric and umbilical regions, whilst dullness was present on percussion in the epigastric region and in the flanks, but this was not extensive. There was some diminution of the liver dullness. Operation was performed two hours after the perforation had occurred.

A free epigastric incision, with displacement of the left rectus outwards, was made. On reaching the peritoneum it bulged forward, and incision gave exit to much gas and a small quantity of fluid. The stomach was dilated and prolapsed. A circular, clean-cut perforation of the size of a sixpenny-bit was found on the anterior and upper surface of the duodenum in its first part. Around it was an area of induration about as large as a penny, and beyond that a circular brown ring, apparently the result of a recent hæmorrhage. Sutures of No. 2 silk were used, a fold of the stomach being drawn across the opening and secured. The peritoneum was washed out with saline, and the incision through the abdominal wall closed in layers. The amount of free fluid was not large, and no suprapubic drainage was required. For a time she had irregular pains about the abdomen and continued pale, but was apparently quite well and taking ordinary food when she left hospital on Nov. 20th. The question of the immediate performance of gastro-enterostomy was considered, but negatived by the anæsthetist owing to the amount of shock shown. Up to the present she has developed no symptoms of pyloric obstruction.

The next case presented more difficulty in diagnosis and in the local management of the perforations.

CASE 2. *Subacute perforation with extensive induration; gastro-enterostomy; drainage through epigastric incision.*—A single woman, aged 28, admitted to St. Thomas's Hospital on Jan. 18th, 1916, stated that she had been awakened in the early morning of the 16th by pain in the upper abdomen, and had vomited. On the 17th she still had the pain, and was kept in bed without food. Not being better on the 18th she was sent to the hospital. On admission she looked ill, but did not appear to be suffering from shock. The abdomen moved poorly on respiration, and deep inspiration caused pain. Tenderness on pressure was present on the right side, chiefly over the upper part of the right rectus; towards the epigastric region this was very marked. On percussion there was an increased amount of dullness over the part corresponding to the area of greatest tenderness. This was continuous with the liver dullness. The resonance in the flanks was impaired, but there was no dullness over the pubes or evidence of much fluid. Pulse 120; temperature 100·6° F.

Operation was performed at 2 P.M. A mesial epigastric incision was made, and the subperitoneal tissue was found in an œdematous condition. Some gas and greenish fluid escaped on incising the thickened peritoneum. When an adherent stomach had been pushed back from the liver, more greenish, turbid fluid escaped, but no ulcer could be seen. The anterior surface of the stomach and duodenum over a circle about 2 inches across had been adherent to the under surface of the liver and peritoneum below it, but posteriorly this adhesion had been broken down, so that some fluid had escaped into the right kidney pouch. The stomach surface involved was irregularly covered with yellow lymph patches, and one of these patches concealed a perforation about the size of a pea, with sharply cut edges. The stomach, lying high and not much distended, had rather thick walls, but the area of induration was not only very rigid, but would not hold unusually thick sutures. A silk suture was passed across the ulcer from side to side, deeply in firm tissue and tied without infolding of peritoneum. Thick catgut stitches were put in, but these were distance sutures to form an extra method of support for the silk suture placed across the ulcer. The peritoneum was cleansed with a gauze sponge; nearly all the greenish fluid was in the right kidney pouch and behind the liver; none was found on the left side or in the pelvis. The transverse mesocolon was opened with the intention of

doing a posterior gastro-enterostomy, but the lesser pouch was almost obliterated by old adhesions, whilst the thickening of the base of the ulcer extended over a large surface of the posterior wall towards the middle of the stomach. An anterior gastro-enterostomy was therefore performed. A gauze plug was packed round the sutured part of the stomach between it and the liver, the end being brought outside below a moderate-sized drainage-tube which passed to the ulcer. The remainder of the incision was closed.

The plug was kept in for two days, the tube for eight days. There was a little discharge from the wound of offensive fluid, smelling of gastric juice, which irritated the skin around, but at the time the tube was removed it was purulent and no longer irritating. The temperature became normal in three days' time, and she was sent to the Schiff Home on Feb. 1st. When seen there on Feb. 22nd she was in excellent health, being able to take food like the other patients without any discomfort. She had gained much in weight.

With a history of prolonged stomach trouble, it was evident that the patient had suffered from a gastric ulcer, and the sudden pain, vomiting, and shock made it probable that the ulcer had given way into the peritoneum two days before admission. It was a little difficult to reconcile this opinion with the condition of the abdomen, because there should have been evidence of more free fluid present. Even a small leaking perforation will almost fill the peritoneum in two days.[2] The dull area with its great tenderness suggested a localised inflammation between the stomach and the liver, but did not quite explain the severity of the peritonism. There can, however, be little doubt that the more acute symptoms were the result of sudden escape of fluid which had accumulated between the stomach and the liver. The stomach wall had then become apposed to the liver and the escape of more of its contents impeded; this had been assisted by the large flake of adherent lymph which concealed the perforation.

The main interest in the case arose from the difficulty experienced in dealing adequately with the perforation, as the extensive induration surrounding it made the use of a fold of the stomach wall quite out of the question. The placing of the suture across the perforation, at some distance from the edges of the opening, enabled us to limit very considerably the escape of gastric juice, whilst the "distance" sutures of catgut prevented tension on it for some hours. The operation of gastro-jejunostomy was required for the relief of the obstruction caused by the disease about the pylorus. It was also required to help in the preservation of the sutures. It carried away most of the gastric juice by an easier route than the one over the ulcer, diminished tension, and enabled us to feed the patient at an earlier date. The amount of fluid which did escape from the wound was quite small.

In all cases the importance of accurate suturing is apparent, and the weakened part must be able to withstand strain from vomiting, coughing, or pressure from distension of the stomach. Should one or more sutures fail and leakage occur after an abdominal incision has been closed and the patient put back to bed, death will ensue from peritonitis within a few hours. If by some rare chance the escaping gastric juice is prevented from a general diffusion, there is a possibility of recovery, but the fistula which results leads to a rapid dehydration of the patient with remarkable emaciation, quite as startling as that resulting from partial strangulation of the stomach[3] in a diaphragmatic hernia. Recovery from this fistula is so rare that the account of such a condition is of interest.

CASE 3. *Perforation of duodenal ulcer; giving way of sutures; formation of fistula; anterior gastro-jejunostomy.*—A police constable, aged 35, was admitted on Dec. 26th, 1914, with a duodenal fistula. He was very ill and unable to answer questions, but it was ascertained from others that he had been admitted to a cottage hospital for duodenal perforation which had been closed by operation on Dec. 11th. His divisional surgeon reported that the man had been under treatment for nearly a year with duodenal ulcer and he appeared to be progressing well until two days before the operation, when he was taken suddenly ill. "At the operation the ulcer was stitched. Up to a point he did well, but the ulcer broke down again, and I think must have entered the transverse colon. The gastric juice passing into the colon gave him diarrhœa which nothing stopped, and anything taken by the stomach intensified it. He was going down hill rapidly. ..... He was practically dying on two occasions. On the 21st the wound gave way and a watery fluid poured out; subsequently food taken by the mouth appeared at the wound unchanged. He had lost flesh with startling rapidity."

Some months before this (July, 1913) he had been under treatment in hospital for dyspepsia, symptoms of which had been present for about a year. Examination with the X rays showed no abnormality at that time.

The patient was a big man who had become extremely emaciated. He appeared very ill, the cheeks were hollow and flushed, the eyes sunken, lips and tongue dry. His weakness was so extreme that he could not turn in bed without assistance, and could hardly speak louder than a whisper. The abdomen was much sunken, the bony prominences were clearly visible, and the whole was a boat-shaped hollow with the umbilicus the lowest point. There was the mark of a recent incision in the epigastric region to the right of the middle line and another at right angles to it running to the right. The vertical wound had healed while the latter was opened up sufficiently to admit the little finger, and a watery, bile-stained fluid flowed from it, which smelt of gastric juice. The skin around was very raw and red for a considerable distance, especially towards the umbilicus, where this fluid had mostly spread as the recumbent position had been usually maintained. He was stated to have lost some 4 st. or more in weight during the fortnight. He was, in fact, almost dried up for want of fluids and nourishment. Pulse 120, weak and small; respiration 20; temperature 98·8° F. He had bedsores over the sacrum.

His general condition was much improved by the administration of saline solution continuously per rectum, so that it was possible to perform the operation of gastro-enterostomy on the following day. An incision was made to the left of the mid-line, at the margin of the excoriated area, and the left rectus muscle drawn outwards. The parietal peritoneum was very firmly adherent to the stomach towards the pylorus. Some of the adherent anterior wall of the stomach was cleared by the separation of recent adhesions until a space of adequate size for the anastomosis was prepared. The operation was performed by the anterior method as it was necessary to be quick and produce as little disturbance as possible. Saline was given subcutaneously during the operation, and a pint of it left in the peritoneal cavity.

By Jan. 11th the watery discharge had ceased and been succeeded by a purulent one of no great amount. He was still very weak and thin, his progress having been hindered by an attack of subacute inflammation of the lung. This attack passed away in about 10 days and he made more rapid progress, but it was a long time before the bedsores healed. He was, however, in very fair health when he left the hospital on March 11th. Even then his weight was only 9 st. 7 lb., although he was over 6 ft. in height. The closure of the fistula appeared to be hastened and his state rendered more comfortable by placing him on his left side during the earlier after-treatment. Plugs soaked in a solution of carbonate of soda were lightly packed in the fistula.

Case 4 represents the most common clinical type as seen after perforation of one of these ulcers when the patient has not come under care early and events have progressed to a more serious extent. The shock of the original peritonism is still evident or the patient may be in a state of collapse, whilst the progressive diffusion of the stomach contents in the peritoneum is an increasing danger. Operation usually saves the patient, but a more prolonged and extensive procedure followed by drainage of the pelvis is required; whilst he is exposed to greater risks during convalescence, especially from pneumonia and subdiaphragmatic abscess. There is sometimes a "period of repose" after the first severity of the symptoms has passed, but operation must not be postponed under an impression that the patient may recover. Free fluid in the flanks as indicated by shifting dullness should warn against such a fatal error. I have seen some distressing results of this "wait and see" policy.

CASE 4. *Perforation of duodenal ulcer; operation; drainage; secondary gastro-jejunostomy.*—A clerk, aged 41, was admitted to St. Thomas's Hospital on Sept. 3rd, 1915, with acute abdominal symptoms of 24 hours' duration. He stated that about three and a half years before he began to suffer from stomach trouble, and on one occasion vomited blood. His chief symptoms were pain after food and flatulence. For nearly the whole of this time he had been placed on a diet of milk. For six weeks he had been much better and free from pain, so that his doctor had allowed solid food. On the evening of Sept. 2nd, when feeling very much better, he was suddenly seized with agonising pain in the stomach region and became weak and collapsed. On admission he was still suffering from shock and severe epigastric pain, whilst his face was pale, cold, and sweating. Pulse 120, very feeble; respiration difficult and slow; temperature 98° F. The abdomen was not moving well, was

[2] The Acute Abdomen, second edition, p. 157.
[3] Ibid.

very rigid, and generally very tender. There was much dullness in the flanks due to shifting fluid.

A median epigastric incision evacuated a large quantity of sour-smelling fluid containing flakes of lymph, but no food particles. Another incision was made above the pubes and a large tube passed into the pelvis, which was full of fluid. The stomach, which was large and much distended, was brought to the surface and a perforation, big enough to admit the index finger, found on the anterior surface of the first part of the duodenum. A tube was passed through this and the stomach emptied; it was not easily passed as the pylorus was much contracted. A double row of No. 2 silk sutures (interrupted Lembert) was inserted to close the perforation, a fold from the stomach wall having been brought across and the peritoneum thoroughly flushed with saline solution. The upper wound was closed and the drainage-tube left in the suprapubic opening. The question of gastro-enterostomy was considered, but the bad state of the patient was against any prolongation of the operation.

On the 9th he was taking solid food, but suffered from flatulence. By the 20th his wounds were quite healed, but he complained more of flatulence and pain after eating anything. No improvement in this respect followed dieting, so it was thought best to do a gastro-enterostomy considering the small size of the pylorus as demonstrated at the operation. On the 24th posterior gastro-enterostomy by the method of Mayo was performed. The region of the perforation looked normal and was without adhesions; no trace of the sutures was seen.

By the 28th he was taking some solid food, and he left the hospital on Oct. 11th, 1915, feeling well but looking somewhat anæmic. He had gained considerably in weight.

In Case 2 the additional operation of gastro-enterostomy was imperative at the time the perforation was sutured; the local conditions necessitated it. Luckily her general state permitted of its performance without adding unduly to the risk. In nearly every instance of perforation of duodenal ulcer, or of ulcer situated at the pyloric end of the stomach, this operation must be considered. In the larger number it is contra-indicated by the state of the patient, who is already suffering as much as he can bear without any addition which is not imperative. In most the operation would have to be an anterior operation, for to open up to infection areas which would not otherwise be exposed would appreciably increase the risk of complications. Usually it is much better for the patient to undergo a gastro-enterostomy by the posterior method at a later date if symptoms of pyloric obstruction arise. In addition, there is a danger of the formation after an uncertain period of time of a jejunal ulcer when the anterior method has been employed. This sequence of events is illustrated by the next case.

CASE 5. *Perforation of jejunal ulcer eight years after anterior gastro-jejunostomy; suture.*—A man, aged 60, was admitted to City Ward on March 15th, 1915, complaining of abdominal distress. His history was that eight years before he had undergone operation in St. Thomas's Hospital for perforated gastric ulcer; six weeks later the surgeon had done an anterior gastro-jejunostomy because of pyloric obstruction. Since the second operation the patient had been quite well until 3.30 P.M. of the day of admission, when he was seized with violent pain in the pit of the stomach, especially on the left side. He vomited three times and felt very ill. He came to the hospital because he thought "something had given way" again. The man looked ill and was in extreme pain. The abdomen moved very little on respiration, was rigid, and a distinct dull area was revealed on percussion, extending down the left side from the level of the hepatic flexure to the anterior superior spine of the ilium. His tongue was coated; pulse, 120; temperature, 100° F.

At the operation six hours after the onset of his illness an incision was made through the upper part of the left rectus. Some turbid fluid immediately escaped. The perforation, which was situated just beyond the line of the anastomosis, had been drawn high up with the stomach. Its position was indicated by the flow of brownish fluid, mixed with small bubbles of gas. It was apparently in the ante-mesenteric border of the gut and admitted the end of a pair of Spencer-Wells's forceps. The gut below was distended and reddened, and there were some flakes of lymph around the perforation. It was closed with two layers of Lembert silk sutures, the second burying the first. The whole abdomen was irrigated with saline, one or two old adhesions clamped and divided, and the wound closed in layers. Recovery was uneventful.

This case taken by itself would perhaps not be of very much value, but the instances of jejunal ulceration following the anterior operation as compared with the posterior are so numerous that the danger cannot be ignored. This is the fifth perforation of a jejunal ulcer after anterior gastro-enterostomy that has been under my care; luckily they have all come under treatment early and recovered. In one patient the tendency to jejunal trouble has been very marked. She had perforation of a gastric ulcer in 1903; operation for pyloric obstruction in 1904 (anterior gastro-jejunostomy); suture of perforated jejunal ulcer in 1905; suture of another perforation in the jejunum in 1906. In September, 1915, she had hæmorrhage from the bowel with some tenderness in the epigastrium and again in February of this year. Otherwise her health has been good, she looks well, has a sound abdominal wall, and lives an active life.

(It may be added that Case 3 since I described it in a lecture has been successfully operated on by Mr. Adams for acute perforation of a jejunal ulcer. This occurrence helps to accentuate the importance of these remarks.)

The sutures in duodenal perforations should be passed by Lembert's method in the direction of the long axis of the duodenum, so that further diminution of the passage may not be induced. If they do not hold in the tissue immediately around the perforation, it may be possible to bring a fold of the adjacent stomach wall across and fix it in position.[4] This method has been proved most useful in more than one instance and its result was seen three weeks later in Case 4. No trace of the suturing remained. The absence of any evidence of former mischief is sometimes remarkable when the abdomen is opened in later life. In Case 5, where a perforation had been sutured and secondary gastro-jejunostomy performed eight years before, there were only a few isolated adhesions. In another man for whom a secondary gastro-enterostomy was recently performed for pyloric obstruction 12 months after suture of a duodenal perforation in another hospital, there were extensive omental adhesions to the anterior abdominal wall. In neither of these men did there remain a trace of the perforation, and the peritoneum covering the duodenum appeared normal.

Case 2 gives an example of a different method of closing a perforation and also shows the importance of gastro-jejunostomy in such cases. It may be possible to secure the perforation by suturing liver or omentum over it, but the insertion of a plug, which would certainly come away in a few hours, leaving a larger opening, does not commend itself; if tried without the performance of a gastro-enterostomy recovery would be most unlikely.

The diagnosis of these perforations cannot be considered here. It is indicated by the records of the cases already given, and will vary according to the stage of the illness which has been reached when the patient presents himself. There is often a close resemblance between the perforation of a duodenal ulcer and the commencement of an acute appendicitis. The very sudden onset in any acute abdominal condition where this difficulty is found should be regarded as pointing to duodenal perforation, although the pain when the patient is seen may be referred to the right lower abdomen.

In a patient, aged 66, seen with Dr. A. Grayling on April 9th of last year the sudden pain occurred as he entered a room in his house dressed ready to go out to dinner. Operation within 24 hours showed a chronic ulcer in the first part of the duodenum which had caused no symptoms giving rise to any suspicion of its existence before perforation occurred. There had been slight evidence of gastric dilatation and some complaint of flatulence. In this case the pain was in the right lower quadrant of the abdomen and was followed by vomiting. There was much free gas in the peritoneum as well as free fluid. Recovery followed closure of the perforation with No. 2 silk (No. 1 cut out) and drainage of both subhepatic region and pelvis.

In another case seen with Dr. C. D. Green on Oct. 26th, 1915, symptoms due to duodenal ulcer had been present for years, but for some time he had considered himself cured. This patient, aged 50, had a sudden seizure of epigastric pain at 11 P.M. accompanied by much shock. He was sent into a cottage hospital and we operated within 12 hours. He was then recovering from shock, but was in great pain. The abdomen, which was very rigid and contained much fluid, was not distended. No. 2 silk was used to close the perforation, the peritoneum washed out, the upper wound closed, and drainage from a suprapubic opening employed. When seen some fortnight later he had no symptoms of duodenal obstruction.

Mr. Arthur Du Cros, M.P. for Hastings, has promised a gift of £7000 to the Extension Fund of the London (Royal Free Hospital) School of Medicine for Women, thus completing the £30,000 for which appeal was made.

ON PNEUMOCOCCAL BRONCHITIS.

BY SIR JAMES GOODHART, BART., M.D. ABERD., F.R.C.P. LOND.,
CONSULTING PHYSICIAN TO GUY'S HOSPITAL, ETC.

IN the past year or two there has occasionally come under my notice a youth of somewhat degenerate development who at some prior period has suffered from pneumonia, or may be an empyema, below the root of the left lung. This has left behind it a patch of solid or condensed lung with a cavity within it from which there occasionally comes a small hæmorrhage, the youth being otherwise healthy. Not inclined to studious habits, it is very desirable that he should become familiar with some suitable outdoor occupation, and that in so doing he should live with some family away from his home. But in such a case there is always this preliminary difficulty. Has he got consumption? If so, A or B, otherwise willing, refuse to have him. That point settled, more or less satisfactorily, there comes another. Is his disease contagious? It is this question, a much more searching one than the other, that makes one pause and think, and induces me to put pen to paper.

So far as I myself personally am concerned I give an unqualified No to both the above questions. He has *not* consumption, and he is not contagious, using that term in its amplest meaning. But I am not writing to air my own opinions, I am simply bent on laying bare the thoughts that pass through my mind when bacteriological questions such as these come up before me, and necessarily this is frequently so. Personally I should have no objection to live with any case of tubercular phthisis, because I am convinced that all experience teaches that provided the observance of the most elementary rudiments of cleanliness and sanitation there is very little risk attached to doing so. The infectivity of tuberculosis, whatever be its nature, is of a low order.

Many years ago, when the bacillary constitution of tubercular foci had but recently come to our knowledge, I wrote an article in the *Medical Magazine*—now, I believe, defunct—the burden of which was "Don't spit." If people are so uncleanly as to spit all over the place, or if smokers, as seems to me their common practice, close up all but the smallest cranny in a railway-carriage when they begin to smoke, I am open-minded enough to believe that many things may be "caught" and even that all sorts of intensive cultivations may go on, and very swedes and mangolds of disease come out of radishes. But given ordinary care and cleanliness, one may live with the tuberculous without risk of infection. But this youth has not tuberculosis—the expectoration has been examined many times and the tubercle bacillus has never been found, and, moreover, the position of the disease is quite against any such assumption, the mischief in the lung is basal. No doubt there are signs of a good-sized cavity, but that is of no great weight, because it is certain time and again from post-mortem demonstration that what has been thought to be a cavity of considerable size during life may be shown to be no more than a bronchial tube dilated to but moderate dimensions, perhaps with some condensation of tissue round it, when one is in the presence of the actual conditions.

But the question that I have put brought to my mind a series of cases that I collected gradually some years ago, and have had by me a long time, where people have been sent to me suspiciously phthisical and yet have proved to be pneumococcal only, or at any rate infected by some other than the tubercular germ, and I may add that it is my conviction that with this knowledge well in mind it is generally possible to distinguish between the two conditions and to say beforehand with tolerable accuracy which of the two will be found upon bacteriological examination. I have notes of some sixty of these cases now before me, and I propose to quote a few of them. Perhaps it should be said *in limine* that since these observations were made many other such have been recorded, and I am quite aware that it is now common knowledge that a pneumococcal infection is a very ordinary thing not only in the pulmonary passages but in almost any part of the body; but perhaps as an independent record these may still be worth mention with such few remarks as I may wish to make in relation to them. The notes of my first case, the one, indeed, that called my attention to the subject, I have most unfortunately mislaid, and the details of it I therefore cannot give, but the patient was a middle-aged somewhat spare man with a chronic bronchial affection that aroused suspicions of tuberculosis, and to my surprise the report came back that the expectoration yielded the pneumococcus in pure culture.

2. A man, aged 40 when he first came under my notice, has been seen from time to time in the last 30 years. He has always looked like a case of phthisis, and he has some little inequality between the two apices, but he has never developed any obvious disease. Tubercle bacilli have never been found, but the little mucus he expectorates contains small numbers of pneumococci and some Gram-negative diplococci.

3. A man aged 36. I saw him first in 1896, when, having dullness all over one side and coarse râles at the apex, I jumped erroneously to the conclusion that he had phthisis. But in 1904 I came across him again, and finding him still alive I then had his sputum examined. There were no tubercle bacilli, but pneumococci in plenty. Once more I saw him in 1908. He had had much chest trouble for many months that he called asthma, but he had gained flesh. His chest was in a very interesting condition, being deep and asthmatic, but all the physical signs were at the *upper* part, and on the right side, where there was much coarse medium râle above the clavicle and down the front and for half-way down the back. There was also plenty of sharp, moist râle along the edge of the sternum, but no evidence of consolidation of the lung. The sputum was still free from tubercle bacilli, and contained plenty of pneumococci, as well as a considerable number of the micrococcus catarrhalis.

4. Here is another case of much interest and, let it be admitted, a doubtful one. An unmarried lady, aged 32, very tall and thin, was seen by Dr. Rayner Batten, of Campden Hill, in 1904 with cough and cold and sharp pain in her right side. It was thought to be pleurisy without a friction sound, and nothing more developing in her chest, she went away. She reappeared in a fortnight with fine râles all over the right chest, the apex more especially, but she had not lost weight, and the sputum, examined on two separate occasions, showed no tubercle bacilli. I examined her at this time, when her right side was deficient in resonance, and *above* the clavicle there came upon coughing a number of coarse râles, *below* the clavicle there were fine and rather sticky râles. She got back to her usual state of health, and six months later came for permission to marry. The chest remained much the same, there were some small dryish râles above the clavicle and below, and in the supraspinous fossa, but they conveyed to me the impression of an unexpanded lung and there was no other evidence of consolidation or disease. I inclined now to think that an old and bad fracture of that clavicle might have something to say as to the want of expansion on that side. Therefore, in the absence of tubercle bacilli to repeated examination, I did not think there was much to be alarmed at, and she was married in the following spring. Seven years later Dr. Batten again asked me to see her. She had gone on much as usual till a month previously when she had been confined of a healthy baby, and since then she had had fever, short breath, and cough, but no expectoration. The sputum, what there was, had been repeatedly examined and no tubercle bacilli were present. My note of her then is as follows: "I should certainly say now that she has apical phthisis, there is so much râle both back and front at the right apex. But it is peculiar that now, as years ago, there is no evidence of consolidation, and I therefore still hold to my original opinion that in the absence of the presence of tubercle bacilli in the sputum the condition is not a tubercular one." I had a further specimen of the sputum sent to me, and it showed staphylococci, streptococci, micrococcus catarrhalis, and diplococci resembling pneumococci, but still no tubercle bacilli. She went into the country, and died there about a month later with cardiac trouble, albuminuria, and lumps in the abdomen, and we heard that the case was certified as "phthisis and abdominal tubercle," but I demur considering that no tubercle was ever found in the expectoration. I think that some intercurrent infection upon the top of a chronic pneumococcal bronchitis is much the more likely, and with the subsequent rapid development of lumps in the abdomen one cannot but suspect that had a necropsy been made we might have lighted upon a surprise even of some other kind.

5. A young Indian, aged 22, had been at Cambridge for three years, where he had had good health. He came to London for an examination, and there he had influenza and congestion on the left side of his chest. The attack would not appear to have been of any severity, but yet it left him without appetite and somewhat broken down. He was out of work until October, when the pulmonary condition failing to clear up he was sent to me. There had been a dry pleuritic rub all round the base of the left lung, and in the axilla, and ultimately on the right side. The sputum examined on three occasions gave a negative result, as did also a Calmette reaction. When I saw him after some six months of ill-health he seemed sound, except that under the

left nipple and round the side to the base—a very suspicious area, it must be admitted, when tubercle is in question—there was a great deal of dry râle, with, at one or two points, a sharp, dry, moist, metallic sound, and there was some slight want of expansion. There was no disease of the apices, and I thought the lungs sound; the dry character of most of the râles made me think that the case was a pneumococcal one. In accord with that opinion, stained films showed considerable numbers of pneumococci and influenza bacilli and small numbers of Friedländer's pneumo-bacillus. There were no tubercle bacilli. Six weeks, and again six months, later he was in much the same condition, there being still a good deal of fine diffused dry râle below the left nipple and into the axilla and back. Pneumococci were still present in small numbers and tubercle bacilli were absent. Six months later still, out in India, his pulmonary condition was as of yore, although he was well in health.

6. A man, aged 35, living much in the healthy parts of India, came home with a high temperature. His brother had died from phthisis years ago. The patient had had influenza a year ago and had never been well since. His right chest was deficient in resonance upon and below the clavicle, and also behind in the supraspinous fossa, and all over this area were coarse, sticky, sibilant râles, especially about the root. The sputum was examined for tubercle bacilli, the influenza bacillus, and pneumococci, but only the pneumococcus associated with the micrococcus catarrhalis was found.

7. A man, aged 59, always subject to colds, had had a bad one for the last nine months. He expectorated much phlegm. The left side was deficient in expansion, and all over the roots of the lungs there was much subdued moist râle. The sputum contained no tubercle, but many Gram-positive diplococci, and the inoculated culture media showed numerous colonies of diplococci, indistinguishable from the pneumococcus.

8. A man, aged 55, a fine healthy specimen of humanity, had double pneumonia after influenza, and was very ill from March to May. Three months later he still had cough, and his expectoration contained both pneumococci and influenza bacilli.

9. A lady, aged 35, got a chill a fortnight before I saw her. She was subject to winter cough, and had lately expectorated a good deal of phlegm. She was sent to me as a case of rapid phthisis, and indeed nothing could have looked uglier than the physical signs. The right side was quite dull in front at the apex; there was less to be heard on auscultation than one expected, but the breathing was coarse and emphysema-like, and I supposed it to be of a complementary character. On the left side fine and coarse sibilant râles could be heard all over the apex and round the nipple. Similar signs could be heard behind, and I supposed the case to be an acute outburst of tubercle, but from the peculiar dry and sticky râles I thought it might possibly be of pneumococcal nature, and so it was. There were no tubercle bacilli and plenty of pneumococci, and she speedily got well.

10. A woman, aged 55, whom I had seen five years earlier with double pneumonia after influenza. She quite recovered from that attack, but a few months ago began to suffer from cough and a thick expectoration. She used the right less than the left side, and at the base there was evidently an adherent and partially collapsed lung. All over this side there was some dry râle, but there was also plenty of good vesicular murmur. I thought her probably suffering from some recent patch of disease in the substance of the lung from which she was recovering, but the nummular character of the sputum looked suspicious of phthisis. However, it contained no tubercle bacilli, but many pneumococci and a few staphylococci.

11. A lady, aged 50, had had influenza four years ago and bronchitis ever since. There was much coarse scattered râle over each lung, but more on the right than on the left side and at the apex than the base, so that the existence of tubercle was possible. Three separate examinations of the sputum at intervals gave a negative result, so the sputum was then examined for pneumococci and the influenza bacillus, and both were found in great numbers.

12. Another but common order of case is this. A young man who all his life has given his relatives much anxiety, because he is such a poor piece to look at; he is always catching cold; occasionally spits a little fleck of blood from somewhere, and he has bad teeth and a dirty tongue—in fact, a capital case for the pyorrhœa-ist to pounce upon and remove all his teeth. He has a granular pharynx also. But although he looks lacking in stamina and a likely subject for tuberculosis, his colds, commencing always in the head and running down into the trachea, do not run the course of the tubercular, and his expectoration, when examined, contains a moderate number of pneumococci, a few streptococci, and the micrococcus catarrhalis, with some Gram-negative bacilli resembling pneumo-bacilli. This man is now "doing his bit."

13. A scraggy, badly nourished boy of 7 1/8 years suffers from febrile attacks and bronchitis and asthma, in which he loses flesh rapidly. He has a fair but rather narrow chest, one side expanding much more than the other, and with many subdued râles. He also has adenoids. His sputum contained plenty of pneumococci, but no tubercle bacilli.

14. Lastly, this case may best serve, perhaps, to show that one must beware of the possibility of making a mistake. A big healthy-looking man, aged 50, had had influenza badly *twice*, and laryngitis with it 15 years ago. Ever since then the slightest cold would fly to his throat, making him short-winded and provoking a quantity of phlegm. He had a harsh, scrapy, rather noisy cough, which made me think of tubercle in his larynx, but perhaps more of aneurysm, but I could find nothing in his chest. His larynx, too, was not like a tubercular one, being intensely injected throughout, and perhaps a little granular. The sputum contained a considerable number of pneumococci and a few of the micrococcus catarrhalis. Tubercle bacilli were not present. He got well and I saw no more of him for a year, when he turned up again with a similar attack. He was still a big, florid, well-looking man. The larynx was again acutely congested, he had the like harsh raucous cough, and after a very careful examination of his chest I could detect no disease. I sent him to a laryngologist, but his friends diverted him to a bacteriologist, who said he had active tuberculosis at both apices, and tubercular bacilli in his sputum. So I give the case as a warning to myself, but at the same time I shall truthfully confess that I wonder if bacteriologists ever make mistakes, and that at the back of my head I think, "Could it have been so here?" This patient died some four years later somewhat suddenly and unexpectedly, the certificate being signed "Tuberculosis."

There can be no need to add to these cases. All the remainder of my series are more or less alike in the information that they yield. I think there is generally a something in the quality of the crepitation that is to be heard that puts one on the *qui vive*, for although it may be confined to one apex and be thus suspiciously like a tubercular invasion, the râles are often dry and rustling rather than consonating. There is no accompanying bronchial breathing or other evidence of consolidation or softening of the lung. This condition is found in people mostly, but not exclusively, of middle age or older; with a frequent or long history of colds or cough; sometimes with a little hæmoptysis; none of them revealing any bacteriological evidence of the presence of tubercle, but all of some other one or more variety of micrococcus or bacillus: a diplococcus resembling the pneumococcus invariably, but also the micrococcus catarrhalis, staphylococci, once the micrococcus paratetragenus, the influenza bacillus, and so on.

A further point is that when the diplococcus alluded to is present it is likely to be very persistent, and to be associated with more or less evidence of bronchial disturbance for a long time. And this statement applies not alone to the pneumococcus but also to the influenza bacillus, and, indeed, accords with what we know of germs in other parts of the body, the bacillus coli, for example, in the genito-urinary tract. Where once they thrive it is difficult to extirpate them. A diplococcus resembling the pneumococcus is the one that never fails in any examination, and the question naturally comes to mind, Is this the diplococcus pneumoniæ, or is it one of several other kinds of diplococcus—now this, now that—and each owning a separate life-history as regards its power of possession? I assume it to be *the* pneumococcus, one and only, but I make no positive statement because this is a question for the expert, and I suspect an extremely open one. I think that if I were a bacteriologist I should have some hesitation in expressing an opinion upon the shades of distinction that differentiate these low orders of being. I indeed expect to be told quite pertinently that one may not be able to distinguish these separate genera unless they be plated out and grown into a more mature shrub. This has been done for me now and then, but one wants to know still more than we do. For instance, are "Gram-positive" and "Gram-negative," "intracellular," and other characteristics, true for each condition of growth in which a particular germ is found, under all the usual variations of cultivation that may occur to it? To put the question more specifically, Are these various strains of diplococci, as has been suggested to me by one bacteriologist, one and the same race of continuous descent, but bred under different circumstances in a slightly different environment, or are they distinct genera, altogether different, one from another and characterising quite different diseases? If they are all of one family, how does the fact bear upon latent activity, epidemic prevalence, and the carrier theory? There is no doubt, for instance, that some cases of pneumonia are highly infective, there are others (? the majority)

that are not so at all. In what lies the difference? In the host or soil? In the germ? In atmospheric conditions (epidemicity?), or what? Clearly from these observations the presence of pneumococci is so common it would be impossible to isolate every one who has pneumococci in his sputum, yet there may be some here and there who have undergone or are undergoing some intensive process who might become dangerous at any time, or at any time be merging into that condition. I should suppose similar musings would apply to the influenza bacillus.

It is thus that the nature of epidemic disease comes before one for it seems not unlikely that some germs have periods of dormancy and activity, and that such oscillations may be a part of the rhythm of their life. It might, on the other hand, be due to the rhythm of the life of their host. For instance, it is possible that at some rhythmic periods of our existence, some recurring time of the year maybe, our economies are engaged in turning out large quantities of what, I suppose provisionally, has been called "antibody," that keeps things quiet. At others our cellars are more or less empty of that commodity. Is it for the lack of some such product that malignant growths are so much the evidence of decadence and decline? And it may well be that some influence of this kind, if it kept full-bodied, might, as Dr. Gordon Goodhart suggests, by its continuous action in the course of time, so modify the disposition of the germ as to destroy its potentialities for evil.

I remember when looking up the question of epidemic influenza some years ago two things struck me: (1) that the disease described in its earliest years was very much the disease that we have had amongst us in recent times; and (2) that it was well-nigh impossible to limit the disease to definite epidemic outbreaks. There are periods when the disease is very prevalent and of great virulence, but when we come to mark the time when the malady for a time ceased to be there is great difficulty in fixing it. The disease rises and falls in prevalence throughout the century (see Creighton's "History of Epidemics,") and it may reasonably be suspected, even if it be not already proved, that worked at from a bacteriological standpoint this would be shown much more conclusively. I think it may reasonably be in question whether influenza, as a *germ*, is ever altogether absent, although its stocks be low and the manifestations of its actions dormant, and, if so, what rouses these germs from time to time into a state of virulence?

Take another point. There are some pneumococci that expend their energies in the old-fashioned way of an acute croupous pneumonia, as it used to be called, but there are many that do not do so, but show up as a pneumococcal meningitis or peritonitis, quite a different sort of disease. I think, too, that it is doubtful if the different kinds of pneumococcal infection are prevalent at the same time, acute pneumonia certainly being more rife in the treacherous weather of spring and early summer.

Akin to the last point is another. It is notorious that some germs have a good time in company. The influenza bacillus and the pneumococcus are frequently found together, and the pneumococcus then seems to flourish the more abundantly, but the staphylococcus and streptococcus are probably in the same ring.

What is the relation of these various growths to each other? Do they simply flourish as weeds side by side, or do they gain strength and activity by the imbibition of each other's juices? Do they even marry and beget half-castes sometimes? We as yet really know so little about the symbiotic fusions of these very lowly organisms of infection, their sisters, their cousins, and their aunts. 'Tis a wise father, indeed, that knows its own child in those walks of life, and it implies no very arrogant imagination to suggest that as these minute beings move about in their infinite number and variety, and possibly velocity, they may so tincture each other and the fluids in which they move as to lead to the maturation, not necessarily in the next generation or even in many, of new sorts of hybrids if we could only be as familiar with them and their progress as we are with that of, say, strawberries or cherries. As a matter of growth or cultivation it would seem that these low organisms may naturally be expected to develop differently according to the medium in which each finds itself, if it can live at all outside its own proper mother liquor. If this be so, is it not thus that hybrids are bred, new varieties of disease develop, and old ones change their type and die out? I have thought this to be possibly the case with enteric fever. This disease of late years has given us quite a different picture from that which was rife, say, 40 years ago, but a case from the front came before me a few weeks ago of quite the old stamp, with its high fever, wild delirium, subsultus, and thickly coated, dry, brown tongue. Intensive cultivation in France on the field of war had revivified the strain and had recalled the worst features of the disease.

In raising all these questions I am quite ready to accept the rebuke of the bacteriologist should he say, "One thing at a time if you please." All I plead for is that in this domain, so new and so subtle, and in which it is so difficult to make adequately intimate observations, all opinions formed shall be considered as purely provisional, whereas I think they are too much otherwise and dogmatic.

As regards treatment in these cases I have not much to say. I record them more for their bearing upon the natural history of disease. A few of them have had vaccines, but none, so far as I remember, with any conspicuous success; but I am, of course, aware that it is in this class of cases that vaccines have repeatedly been recorded to have given remarkably good results. One man of my acquaintance did indeed have not one course but several, and he considered that he obtained considerable relief from them, and I suppose his opinion was worth more than mine as the experience was his; but to my eye, the case being one of advanced emphysema and dilated heart, with probably considerable fibroid changes in the lungs as well, no remedial agents seemed to promise any material relief save relegating him to some warmer and sunnier climate where his reduced pulmonary area would be of less importance, and where he would have more chance of making both ends meet. This being impossible he died not long afterwards.

As regards the value of vaccines in these cases I am strictly neutral and awaiting further knowledge, but I do say that for colds and catarrhs, indeed I might say for pulmonary affections of all kinds for which vaccines or inoculations have been advocated, such methods have not yet passed out of the range of experiment, and I do not feel that in giving advice I am as yet in a position to say more.

There can be few who are more interested in these new lines of investigation from a scientific standpoint than I am. When one thinks of the many natural forms of immunity that are brought about by the exanthemata; the changes that are wrought in the body by vaccination, by inoculations of one sort and another; when we go to plant life and see the wondrous things wrought by graftings and by manures of this sort and that; how in growth and culture resistances are thus formed in one direction, facilities in that, one cannot but see that there is good ground for experiments of this sort in all directions, and to justify great hopes of well-established and strong lines of successful treatment being their outcome in the future. But up to now I can hardly think the position of affairs is satisfactory. Many of these methods are put upon the market far too early; they are recommended by some because they are supposed to know, and are accepted dogmatically in place of tentatively; and a public impatient of disease and eager to take any short cut for its removal thus is liable to misconceive the true position of things. I would that these infant physiological processes could be kept in the background of the nursery longer, and that when allowed to come downstairs they should still be kept strictly within the leading-strings of experience and of scientific observation. That they are not so is, I think, the reason that they are often prematurely and inconsiderately banned altogether. Animal extracts are, I suspect, not adapted to everybody, nor are they for everyone to administer. A large experience is needed to minimise the risk of doing harm, and a still larger one to be able to follow the path and the effects of these substances through the system. The physician would seem to need to combine the attributes of the well-trained bloodhound and an archbishop to track these spirit-like emanations as they course through our vitals. No novice need apply.

THE Royal Humane Society have awarded a bronze medal to Dr. Alan McDougall, medical superintendent of the Epileptic Colony at Sandle Bridge, near Alderley Edge, Cheshire, for rescues effected on the occasion of an ice disaster.

BLOOD FINDINGS IN EPILEPSY.

BY RALPH H. SPANGLER, A.B., M.D.,
CHIEF OF MEDICAL CLINIC, METHODIST EPISCOPAL HOSPITAL, PHILADELPHIA.

DURING the past five years I have had the opportunity in private practice to study the blood of 369 epileptic patients. Careful records have been kept, and occasion is now taken to summarise these observations in the hope of drawing some deductions which may be of value in this interesting, but little understood, affliction.

Blood examinations were made of each patient. Counts of the red and white cells and estimations of the hæmoglobin were made 485 times; differential leucocyte counts were made 4760 times; the alkalinity of the blood was estimated 324 times, and more than 9000 coagulation tests were made. For various reasons it was impossible to make complete and uniform observations in all of the cases. However, in a series of 100 cases the hæmoglobin was estimated, a red and white count taken, and 2264 differential leucocyte counts made. There were in this series 39 female patients, whose ages were divided thus: 11 patients were between 10 and 20 years of age, 14 were between 20 and 30 years, 8 were between 30 and 40 years, 5 were between 40 and 50 years, and 1 was over 50 years. Sixty-one males, giving the following ages, completed this series, as follows: 2 were under 10, 16 were between 10 and 20, 17 between 20 and 30, 19 between 30 and 40, 4 between 40 and 50, 2 between 50 and 60, and 1 over 60 years of age.

Before enumerating the blood conditions found, I would call attention to the fact that the 100 patients in this series came from 36 different States, that not one of them was an institutional case, and that all of them were from well-to-do families; consequently the influence of locality, climate, poverty, lack of nutrition, and environment can be eliminated in considering my findings.

Hæmoglobin.

In the series of 100 cases the hæmoglobin averaged 84 per cent. (Dare's hæmoglobinometer). The lowest percentage was 65, and occurred in a 65-years-old male patient. The highest percentage was 100, and was found in a 27-years-old male. The hæmoglobin in this series of 100 patients was as follows:—Males: 16 cases ranged between 90 and 100, 24 between 80 and 90, 15 between 70 and 80, and 6 between 60 and 70 per cent., the hæmoglobin in the 61 males averaging 86 per cent. Females: 2 cases ranged between 90 and 100, 20 between 80 and 90, 15 between 70 and 80, and 2 between 60 and 70 per cent., the hæmoglobin in the 39 females averaging 81 per cent.

These findings are at variance with a series of cases recently investigated by Fackenheim (Congress for Internal Medicine, Wiesbaden, 1914), who found in 67 per cent. of his cases a diminution of hæmoglobin to between 50 and 60 per cent. In 31 per cent. of his cases it was between 60 and 70 per cent., and in only 2 per cent. was it as high as 80. The difference between my findings and the observations of Fackenheim may possibly be explained by the social status of the patients studied. My experience, however, indicates that the affliction (epilepsy) itself, everything else being equal, produces no decided reduction in the hæmoglobin.

A series of estimations was made to determine the effect of an attack on the colour pigment of the blood, and while in a number of cases there appeared to be a slight reduction of between 5 and 10 per cent., in other cases the reduction was very slight, if any, and promptly returned to normal for that individual shortly following an epileptic seizure.

The Erythrocytes.

The average number of erythrocytes for the 100 cases was 4,640,037. The lowest count showed 3,396,000 per c.mm. in a 45-years-old female patient; the highest count gave 6,400,000 in a 29-years-old male patient. About one-tenth of the cases showed more or less crenation of the red cells, but only in 5 per cent. of the cases were there present a correspondingly large number of poikilocytes or microcytes. This again is at variance with Fackenheim and others who have reported these changes commonly present, as well as nucleated reds, in as high as 85 per cent. of their cases. Here again the social status of the patients of my series doubtless explains in part at least the difference in the morphology of the erythrocytes.

The Leucocytes.

In this series of 100 cases the leucocytes ranged between 3650 and 9360 during the interparoxysmal periods. Shortly after attacks they varied from 5620 to 37,550 (see Table I.). A *daily* leucocyte count was made in 10 cases of the series; in some cases a count was made at varying intervals after a seizure until the white cells were found to approximate the normal number for the individual under study. The length of time required to accomplish this reduction to the normal varied from 12 to 48 hours as shown by the following table.

TABLE I.

Case No.	Between attacks.		Following attacks.	
	Low.	High.	Time.	Count.
1	36,550	75,000	5 minutes.	11,860
2	5,962	9,360	6 hours.	12,500
			12 ,,	9,680
			18 ,,	6,240
3	5,680	7,820	24 ,,	24,760
4	5,620	6,560	9 ,,	10,920
5	5,620	6,880	20 minutes.	8,420
			1 hour.	9,680
6	4,320	7,960	2½ hours.	11,080
			14 ,,	18,120
			22 ,,	14,680
7	4,060	7,180	6 ,,	15,360
			18 ,,	9,680
8	5,620	8,187	12 ,,	37,550
			24 ,,	15,312
			36 ,,	10,620
			48 ,,	9,996
9	5,620	6,812	30 ,,	10,060
10	5,900	7,680	15 minutes.	13,000
			30 ,,	11,560
			12 hours.	5,620

The findings in this series of leucocyte counts indicate that epileptic seizures are followed by a varying degree in the number of leucocytes per c mm. in the peripheral blood. This condition is not constant, however, even though none of the cases studied failed to show such increase. Following one attack the increase may be slight, while following another in the same patient it may be decided. Neither does the degree of increase in the leucocytes bear any ratio to the severity of the convulsive paroxysm. At times the very slightest seizures, with only mild tonic convulsive movements, were followed by an increase in the number of leucocytes to 13,120 per c.mm. At another time two severe attacks closely following one another, with violent tonic and clonic spasms, showed an increase in the white cells of from 5800 before the seizure to only 8000 after the attack. As a general rule, however, my experience would indicate that an epileptic attack developing in an otherwise healthy subject is almost invariably followed by a temporary leucocytosis.

Differential Leucocyte Counts.

An analysis of the differential leucocyte counts in this series of 100 private cases of epilepsy is unique in so far as it has been possible to correlate these findings with reports furnished by the literature. The following table summarises my findings:—

TABLE II.

Cell.	Normal range (Howell).	Range in 100 cases of epilepsy (Spangler).			
	Percentage.	Within normal limit.	Above normal limit.	Below normal limit.	Average for 100 cases (present series).
		%	%	%	%
Small lymphocytes ...	20–25	39	51	10	27·11
Large lymphocytes ...	1 or less	2	98	—	9·31
Polymorphonuclear ...	60–75	59	3	38	60·10
Eosinophiles	4 or under	88	4	8, absent	2·19
Transitionals	2–10	13	—	87	0·78
Basophiles	1 or less	31	28	43	0·51

Howell[1] gives a range of 20 to 25 per cent. as what may be considered normal for the small lymphocytes. It will be noted in the above summarised table that 39 per cent. of the cases fell within these normal limits, while 51 per cent. were above the normal range and 10 per cent. fell below it. However, the average of the small lymphocytes for the series was 27·11 per cent., which average corresponds closely to Howell's high normal limit.

The large lymphocytes, according to Howell, are normally 1 per cent. or less. In this series only 2 of the 100 cases fell within the normal limit, while 98 of them gave counts above this physiologic range. The average per cent. of large lymphocytes in the differential counts for the 100 cases was 9·31 per cent.—a decided enough increase to be suggestive of clinical significance. The large lymphocytes in one differential count of the series reached 23 per cent.

In this series the polynuclear leucocytes fell within the normal range (60 to 75 per cent.) in 59 of the cases. In only three instances were there multinuclear elements above 75 per cent., while in 38 per cent. of all differential counts made the polynuclear cells were found to equal less than 60 per cent. of the leucocytes present. The average for the series was 60·1.

The eosinophiles, regarded by Howell as being a subdivision of the polymorphonuclears, were within the normal limits of 4 per cent. or under in 88 of the cases. An eosinophilia of 5 per cent. was observed in only 4 of the 100 cases studied, and in 8 of the differential counts eosinophiles were not found while counting 200 leucocytes.

The basophiles and transitional forms fell within what may be regarded as the normal range.

Clotting Time of the Blood.

During the past three and a half years I have studied carefully the clotting time of the blood in each case of epilepsy that I have had the privilege of examining. A review of case records shows that more than 9000 clotting time tests have been taken. A Boggs coagulometer was used in making all of these tests, and in order to eliminate variation in personal equation and to have as uniform results as possible, I made all the tests myself.

In a previous series of 18 cases reported[2] the average clotting time was 3·04 minutes. The longest clotting time in that series was 4 minutes; the shortest one 1·5 minutes. In the present series of 100 cases the average clotting time was 3·14 minutes. The longest clotting time in any case of this series was 6 minutes, the shortest 1·5 minutes. In the tests referred to all estimations were made during the interparoxysmal periods, and before any treatment was instituted.

The average normal clotting time of the blood with the Boggs instrument is given by Hinman and Sladen[3] as being 5 minutes 6 seconds. It is generally admitted, however, that under normal conditions comparatively wide variations in the clotting time of the blood may be found in the normally healthy individual, when any of the established methods for determining the same are employed. Some workers with the Boggs instrument have made the normal limit between 3 and 8 minutes.[4]

The fact that the normal limit varies makes the findings above reported all the more significant. It has been conclusively proven to my mind that all cases of so-called essential epilepsy invariably show the phenomena of decreased clotting time of blood. The fact that this time in some cases falls within the limits of what may be regarded as normal, say 3 to 8 minutes with the Boggs instrument, does not prove that the epileptic's clotting time is perfectly normal and not abnormally short. On the contrary, in the present series of 100 cases the clotting times were divided as follows: 7 fell between 1 and 2 minutes, 45 between 2 and 3 minutes, 33 between 3 and 4 minutes, 13 between 4 and 5 minutes, and 2 between 5 and 6 minutes.

These findings indicate that in only 2 per cent. of the cases did the clotting time during the interparoxysmal period exceed the normal average of 5 minutes and 6 seconds. In 98 per cent. of the cases it was below the normal average, and in 52 per cent. it fell below the shortest limit of what is considered the normal range (3 to 8 minutes).

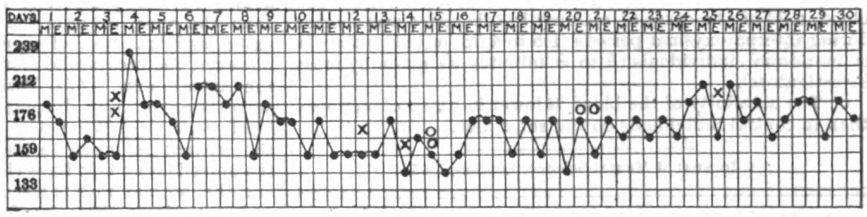
These findings are largely in accord with those of Dr. John Turner,[5] who made extensive investigations into the clotting time of the blood in epilepsy, with the following conclusions:—

"(*a*) The average rate of coagulation is greater in severe cases of epilepsy; (*b*) the rate is quickened during the period that the patient is having fits (serial epilepsy); (*c*) there is a further quickening of the coagulation rate up to 24 hours before a seizure; (*d*) from 24 to 48 hours after a fit there is a rebound and retardation in the rate of blood coagulation."

Alkalinity of the Blood.

The alkalinity of the blood was tested in a series of 21 epileptic patients and in 3 control cases. These patients and control cases were all eating the same diet, which was a general mixed one consisting essentially of fruits, cereals, green vegetables, eggs and milk, with meat only once daily. The patients were 14 males and 7 females. The control cases were all males. These was a total of 324 tests made. The blood was taken daily between 10 and 11 A.M. in each case, and in 5 of the patients and 2 of the control cases the tests were also made between 7 and 8 P.M. A general summary of the results is given in Table III.

TABLE III.



21 Epileptic Patients.

Case.	Lowest.	Highest.	Average.	Case.	Lowest.	Highest.	Average.
1	159	212	171	12	140	212	176
2	133	184	163	13	176	266	196
3	212	239	196	14	156	212	185
4	140	239	174	15	159	159	159
5	140	212	167	16	184	196	188
6	186	239	213	17	140	212	159
7	180	212	196	18	159	176	167
8	133	212	174	19	212	212	212
9	140	266	176	20	218	218	218
10	133	176	159	21	176	256	239
11	176	239	212	Patients' general average, 186			

Control Cases.

22	176	266	214	24	218	218	218
23	176	239	204	Controls' general average, 212.			

The Dare hæmoalkalimeter was used in making the tests. According to the Dare method 2 cm. of normal blood is neutralised by 2 c.c. of reagent, or 266 milligrammes of sodium hydrate to 100 c.c. of blood. Therefore, the 266 point line is considered as normal in the above tabulation and in the following chart. It will be noted that, with the diet used, the general average for the control cases was 212, or 54 points below the normal average, while the general average for the patients was only 186, or 80 points below the normal and 26 below the control cases. Only twice in all the tests did the alkalinity of the patient's blood reach the normal height of 266. By comparing the alkalinity of a patient's blood at the time of an attack with the alkalinity at times when no seizure occurred, it was found that while the general average alkalinity in interparoxysmal periods was lower than the normal average as established by Dare, and also lower than the control cases by 26 points, nevertheless on days when seizures occurred it was found that the alkalinity of the blood was not appreciably influenced by the attack. To illustrate I will cite one case in detail.

Variations in alkalinity of the blood in relation to attacks. o = Slight attack; x = severe attack. (266 is considered the normal point.)

[5] Journal of Mental Sciences, London, October, 1908.

The patient was a male aged 40, and the duration of epilepsy was ten years. Physical condition good. The patient's father, who had died at the age of 55 years from jaundice, had been subject to epileptic attacks at long intervals for 19 years. His mother was living and well, and in her sixty-eighth year. The patient was the fourth child in order of birth; no accidents or injury of head. Between 20 and 30 years he had used alcohol to excess. The epileptic history showed that he had had his first convulsive attack when 30 years of age. He had had from two to four major attacks a month since, and for several years had also had series of petit mal attacks, from two to eight in 24 hours, recurring from two to ten days apart, and a mild attack was often followed by a few minutes of automatism, and the mental confusion frequently lasted from 10 to 20 minutes.

The diagrammatic chart shown on the preceding page illustrates in detail the variations in the alkalinity of the blood in relation to the attack.

In some respects my experiences coincide with those of Pugh,[6] who made studies of the alkalinity of the blood in epileptic patients by using Wright's method. His general conclusions were as follows:—

"The alkalinity of the blood undergoes marked changes in epilepsy. (*a*) It is below normal during the interparoxysmal period. (*b*) It undergoes a further diminution after the fit is over. This after diminution depends upon the length of time, the severity of the muscular spasms, and the degree of alkalinity in the interparoxysmal period. (*c*) It undergoes a sudden and pronounced fall immediately prior to the onset of a fit. (*d*) There is a gradual return of the blood to its normal alkalinity which takes place in five to six hours. (*e*) There is a relationship between the degree of alkalinity and the onset of the fits—e.g., the higher the alkalinity the less liable is the patient to have a fit."

My experience in an investigation of 24 cases, with the Dare method, indicates: 1. The daily average alkalinity of an epileptic's blood is invariably below that of a control individual using the same diet. 2. An epileptic attack, in my experience, causes no further diminution of the alkalinity of the blood nor does the severity of the convulsion (muscular exertion) have any modifying influence. 3. A night and morning estimate of the alkalinity for a month, during which period both major and minor seizures occurred, failed to demonstrate any noteworthy modification of the alkalinity either before or after either form of seizure.

General Conclusions.

1. The percentage of hæmoglobin in epilepsy is comparatively high (84 per cent. in the present series of 100 cases).

2. The red cells show no marked diminution and, with few exceptions, no evidence of degeneration in cases of uncomplicated epilepsy.

3. The white cells in cases of epilepsy fall within the normal limits during the interparoxysmal periods; uniformly, however, there is a tendency to leucocytosis, and at times a hyperleucocytosis at the time of, and frequently for 24 hours following, an epileptic seizure.

4. The average percentage of the small lymphocytes and the polymorphonuclear cells in the 100 cases fell within normal limits; the large lymphocytes averaged 9 per cent. above the normal range; there was no evidence of eosinophilia.

5. The clotting time of the blood is shortened before an epileptic seizure. The range of the clotting time of the blood in 98 of the cases of epilepsy in this series was shorter during interparoxysmal periods (1·5 to 4·75 minutes) than it is in normal individuals (3 to 8 minutes as given by most investigators).

6. The alkalinity of the blood is lower in cases of epilepsy than in control individuals on the same diet.

[6] Journal of Mental Science, London, 1903.

Mr. David Hooper, F.C.S., F.L.S., late curator of the Industrial Section of the Indian Museum, Calcutta, has been elected President of the British Pharmaceutical Conference. He assisted in the compilation of "Pharmacographia Indica" and "Materia Medica for India," has been "quinologist" to the Madras Government, and has made many valuable contributions to scientific journals upon botanical and chemical subjects. The Conference is to hold its annual meeting on July 19th. Mr. Hooper has been elected in place of Major E. Saville Peck, who has resigned in consequence of the increasing pressure of military duties, while Mr. J. C. Umney, the Acting President, is resigning the office under medical advice.

THE SIGNIFICANCE OF PRESYSTOLIC CARDIAC MURMURS.

BY THOMAS LUMSDEN, CH.B., M.D. ABERD.,

DEPUTY MEDICAL EXAMINER, LONDON COUNTY COUNCIL; DEPUTY CHIEF MEDICAL OFFICER, LONDON FIRE BRIGADE, METROPOLITAN WATER BOARD, AND L.C.C. TRAMWAYS.

OF presystolic murmurs audible at the cardiac apex I recognise three varieties: (1) Flint's presystolic murmur, due to aortic incompetence; (2) "stenotic" presystolic murmur, due to mitral stenosis; and (3) "astenotic" presystolic murmur of doubtful origin. It is of great importance to differentiate between these, since they vary widely in etiology, significance, and results. The first two classes are very serious conditions, the third is of comparatively little moment.

1. *Flint's presystolic murmur* is mechanically produced by the regurgitation of blood through the incompetent aortic valve; it is of frequent occurrence and of serious import, an absolute bar to life insurance or to any heavy work. A man who has such a murmur must not be accepted as a motorman or in any other capacity in which his sudden fainting would endanger himself or others. This murmur is recognised by the following characteristic signs: (*a*) An aortic diastolic murmur is audible. (*b*) The second sound at the apex is not reduplicated, but is immediately followed by the presystolic bruit, leading up to the rather abrupt first sound. (*c*) Dyspnœa and palpitation are very marked after exertion. (*d*) There are signs of cardiac enlargement. (*e*) A presystolic thrill may be palpable.

Presystolic murmurs not produced as above by aortic regurgitation are caused at the mitral valve, and may be separated into two classes which I propose to name "stenotic" and "astenotic."

2. *Stenotic presystolic murmurs* result from narrowing of the mitral valve. This is a serious form of heart disease only second in gravity to aortic incompetence, and therefore in a general way more dangerous than either aortic stenosis or simple mitral regurgitation. In these cases we find: (*a*) A murmur presystolic in time, rough and vibrant in quality, of gradually increasing intensity till it ends abruptly in a sudden short and sharply accentuated first sound. (In late stages of this disease the first sound may be represented by a systolic murmur, and finally, as dilatation of the heart increases, the presystolic murmur itself may disappear, and then only a systolic murmur remains.) (*b*) *On palpation* of the præcordial region the apex beat is found to be heaving and widely diffused; its point of greatest intensity may be displaced outwards if dilatation is present and downwards if the heart is hypertrophied. A marked presystolic thrill is felt ending abruptly in a sudden systole, after which the heart recedes from the hand rapidly, almost instantaneously. (*c*) The præcordial dullness may be, and generally is, enlarged. (*d*) Besides the murmur described above we find the second sound reduplicated, since the high pressure in the lung vessels causes the pulmonary valve to close before the aortic valve. From the same cause it is found that the second sound is always accentuated at the pulmonary valve area. (*e*) The presystolic murmur is conducted upwards from the apex towards the base, but not outwards to the axilla, as in the case of systolic murmurs. In some cases, however, the presystolic murmur is very narrowly limited to the apical area. (*f*) Patients who suffer from mitral stenosis are usually dyspnœic and incapable of performing hard work. (*g*) When the pulse is carefully counted and the patient is made to ascend a stair of some 20 steps the pulse is found to have risen 30 or 40 beats per minute, and the normal rate is not resumed till well over a minute, and sometimes three or four minutes elapsed before the original rhythm returns.

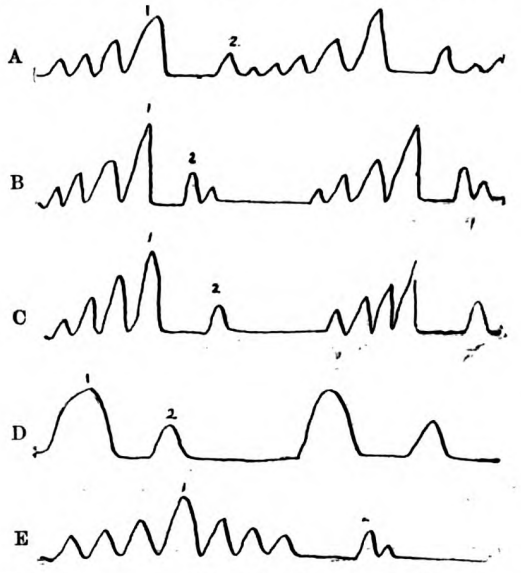
This is a test to which I attach great importance; it is not by any means characteristic of this particular form of heart disease alone, but simply indicates the value of the heart as a working organ, and I use the test as a means of judging the state of the cardiac muscle when the heart sounds are normal or nearly so, and especially with a view to advising as to the safety or otherwise of a patient to whom it is proposed to administer an anæsthetic. If this test were invariably applied I believe many deaths from anæsthetics would be avoided, as in a

considerable number of cases fatality results not from valvular conditions which can easily be appreciated, but from heart muscle weakness (fatty or fib-oid) of whose existence the stethoscope does not inform us. In the test described above the normal pulse-rate should return in from half to one minute; if it does not do so an anæsthetic should only be given if an operation is essential to life, and even then with every possible precaution. (If it is inconvenient to send a patient upstairs for the above test, the same results follow from touching the toes 12 times, which represents about the same amount of work done as when the body weight is raised up the height of a stair of 20 steps.)

3. "*Astenotic*" *presystolic murmurs.*—The doubtful cases from an insurance point of view are such as: (*a*) Occur in apparently healthy patients who are capable of hard work. (*b*) These murmurs are definitely presystolic in time and end abruptly. (*c*) The second sound is not reduplicated, showing that there is no increase of pressure in the lung vessels. And for the same reason (*d*) the pulmonic second sound is not accentuated. (*e*) There is no enlargement of the heart, and the apex beat is therefore normal in position. These murmurs are possibly due to a roughening or slight crumpling of the mitral valves insufficient to cause either stenosis or incompetence. (*f*) There is usually to be felt a presystolic thrill; in fact, if the apex beat can be felt at all in these cases a thrill is always palpable. Exercise or nervousness by increasing the heart's action may accentuate this astenotic murmur, but sometimes, on the other hand, it diminishes on exertion. Nervousness always rather increases it, but never entirely produces it.

I regard these murmurs as comparatively unimportant for the following reasons: They are not accompanied by cardiac enlargement or dilatation. They exist in people capable of hard work and in whom when my stair test is applied the normal rate returns in less than one minute. They are not accompanied by accentuated pulmonary second sound or by reduplication of the second sound, since the mitral valve not being narrowed there is no increased pressure in the pulmonary artery, and the circulation is not delayed or dammed back.

It comes, then, to this. A presystolic murmur not due to aortic incompetence and which is accompanied by signs of delay in the blood's entrance into the left ventricle is due to stenosis and is dangerous. Simple presystolic murmurs not so accompanied are comparatively unimportant. Sir Thomas Barlow, with whom I happened to talk on this "presystolic" question, lays much stress on the condition of the right auricle and ventricle. Any enlargement of these, indicated either by increase of the cardiac dullness towards the right or by marked epigastric pulsation, is, of course, a very clear indication of the increased resistance due to actual mitral stenosis, and if present, would denote the stenotic nature of the murmur.



—	Flint's presystolic murmur.	Stenotic presystolic murmur.	Astenotic presystolic murmur.
Second sound at apex	Not reduplicated.	Reduplicated.	Not reduplicated.
Pulmonic valve second sound	Generally normal.	Accentuated.	Normal.
Aortic valve second sound	Diastolic murmur.	Normal or lessened.	Normal.
Response to stair test ...	Very bad.	Bad.	Good.
Cardiac dullness	Always enlarged.	Generally enlarged.	Never enlarged.
Dyspnœa	Marked.	Easily induced.	Normal.
Palpitation ...	Characteristic.	Easily induced by excitement or exertion.	Normal.
Apex beat ...	Displaced.	Usually displaced, but only slightly till later stages.	Not displaced.
Other murmurs	Aortic diastolic. Mitral systolic may be present in late cases.	Systolic mitral murmur comes in late cases.	None.
Thrill	Usually.	Always.	Always.
Right ventricle	Normal at first.	Enlarged.	Normal.

The differences between the three varieties of presystolic murmurs may be tabulated as shown.

It is most important from an insurance company's point of view that these cases should be carefully differentiated, but when the examiner is in any doubt it is wiser to treat all presystolic murmurs as serious than to risk accepting even at an increased premium patients suffering from so serious a condition as either mitral stenosis or aortic regurgitation. Even when after most careful examination it is ascertained that it is a case of "astenotic" presystolic murmur I recommend that several years should be added to the age of the patient when calculating the premium he ought to pay, since I believe many of these cases have slightly abnormal mitral valves which are more apt to become incompetent than a normal valve. The number of years to be added must depend on the particular case, but should never be less than five. "Astenotic" cases can, however, be accepted for any ordinary occupations and even for posts of such importance as tramdrivers, chauffeurs, &c., since fainting is never a symptom of this condition *per se*. The existence of this murmur is not a bar to military service, nor to any form of sport or exercise.

I have, after making inquiry, found such divergence of opinion on this subject, that it may be of interest and value to give the results of my own very considerable experience as a medical examiner in the hope of clearing up to some extent the points in dispute.

The murmurs here discussed may be diagrammatically represented as below: (A) Flint's murmur; (B) Stenotic

presystolic murmur; (C) Astenotic presystolic murmur; (D) Normal heart; (E) Stenotic presystolic and systolic murmurs.

Or the sound may be imitated by pronouncing: (A) Flint's: Frrip, dupfrrrip, dupfrrrip; (B) Stenotic: Frrrip, dupup; frrrip, dupup; (C) Astenotic: Frrip, dup; frrrip, dup; (D) Normal: Lub dup; lub dup; (E) Stenotic and systolic: Frrripwhist dup; frrripwhist dup.

South Eaton-place, S.W.

LITERARY INTELLIGENCE.—The third edition of Bosanquet and Eyre's "Serums, Vaccines, and Toxins in Treatment and Diagnosis" is announced for immediate publication by Cassell and Co., Limited. The volume has been subjected to a thorough revision and enlargement, while the bacteriological lessons taught by the war receive due attention.

THE INVALID CHILDREN'S AID ASSOCIATION.—The annual meeting of this association will be held, by kind permission of the Speaker and Mrs. Lowther, at the Speaker's House, Palace of Westminster, on Wednesday afternoon, May 10th, at 3 o'clock. His Eminence Cardinal Bourne will preside, and Major H. S. Souttar, Miss Geneviève Ward, and Sir Melvill Beachcroft will be among the speakers. Applications for tickets should be made to the secretary, 69, Denison House, 296, Vauxhall Bridge-road, Westminster, S.W.

Clinical Notes:

MEDICAL, SURGICAL, OBSTETRICAL, AND THERAPEUTICAL.

NOTE ON A TYPHOID CARRIER.[1]

BY S. F. DUDLEY, M.B., B.S. LOND.,
STAFF-SURGEON, R.N.; MEDICAL OFFICER IN CHARGE OF LABORATORY, R.N. HOSPITAL, CHATHAM.

BETWEEN April, 1911, and March, 1914, H M.S. *Formidable* serving in the Home Fleet returned 28 cases of enteric fever at a time when other ships were remarkably free from this disease. These cases occurred singly at irregular intervals, in any part of the ship, and in various ports. The drainage, water, and food-supply were, after an exhaustive investigation, found to be above suspicion. Ships serving under identically the same conditions returned clean sheets as regards typhoid. Practically the only other possible cause of the epidemic in the *Formidable* was that a carrier was present in the ship. The ship was free from enteric before April, 1911, therefore this carrier must have served in the ship since that date, or taking the earlier cases to have had some other origin, the carrier might be one of the original cases of typhoid who had returned cured to the ship. These facts reduced the search to those who were serving in the ship before April, 1911, and to those who had had enteric fever whilst serving in the ship, about 50 men in all. All these men had their blood examined for agglutination against B. typhosus and their urines and fæces bacteriologically examined for B. typhosus. No B. typhosus was isolated from any of their excreta on the first investigation, but one man gave a marked positive Widal reaction. He was re-examined three times and it was only on the third examination that B. typhosus was isolated from his fæces. This case has the following history:—

During October, 1898, the man was sent to Royal Naval Hospital, Chatham, suffering from enteric fever. In 1899 he had dysentery in China, otherwise he has not had a day's illness since. He is a strongly built, big man, 39 years old. He has no signs or symptoms of gall-bladder or any other trouble. His rating in the navy is ship's cooper, and his work brings him in contact with articles of food when he breaks open casks and cases and assists the ship's steward in serving out these rations to the crew.

Below is drawn up a list of ships which the man had joined, the date he joined each, and the cases of enteric fever (diagnosed definitely as such) that occurred in the ships during the time he was employed in them. Fatal cases, when mentioned, have also been noted. This list is compiled from an examination of the medical journals of the ships. The cases were, of course, spread round many hospitals all over the world; hence this table is probably very incomplete as regards deaths, and under-estimation of the actual number of typhoid cases is also probable, as in looking through the records in the ships' journals many cases of enteric may have been missed amongst such entries as simple continued fever and pyrexia.

Table Compiled from the Journals of the Various Ships.

Ship.	Date of joining.	Place where serving.	Cases of typhoid.	Died.
Pembroke	June 15th, 1898.	Home.	—	?
Orlando	Feb. 15th, 1899.	China.	2	?
Pembroke	July 26th, 1902.	Home.	5 (12)	?
Immortalité ...	Aug. 27th, 1903.	Home.	1	1
Endymion	Jan. 18th, 1905.	Home.	1	1
Albion	May 8th, 1906.	Channel.	1	—
Majestic	Feb. 26th, 1907.	Home.	2	?
Venerable	Jan. 7th, 1908.	Channel.	4	?
Implacable	Feb. 2nd, 1909.	Atlantic.	6	2
Pembroke	April 1st, 1910.	Home.	2	?
Cæsar	June 7th, 1910.	Home.	1	?
Formidable	April 4th, 1911.	Home.	28	7
Totals			53	11

Entered the Naval Hospital, Chatham, on April 24th, 1914.

Of the 12 cases in the *Pembroke* during the time this carrier was in the naval barracks, 5 are noted as occurring actually in the barracks and no history of the infection could be obtained at the time; the other 7, however, were reported to have contracted the disease when on leave. All the other cases since 1902 occurred at times when the rest of the fleet was remarkably free from this disease and no source of infection could be discovered. The 4 cases of enteric fever in the *Venerable* in 1908 developed the disease on the following dates: (1) Jan. 9th; (2) Jan. 31st; (3) July 23rd; and (4) Dec. 14th. The medical officer of this ship, writing at the time, notes that Case 3 had not been ashore for one month, and that Case 4 had not been on leave for two months. Six cases were reported from the *Implacable* in 1909; there were two cases only of enteric fever in the rest of the Atlantic Fleet, whose average strength for that year was 9020 men. In his journal for 1909 the fleet-surgeon of the *Implacable* wrote: "I have tried to trace how these men got the disease, but failed. It is quite possible there may be a carrier in this ship, as some cases occurred in the *Venerable* from which this ship's company came. I have gone through the medical history sheets and find there are 4 men who have had the disease in the last three years. When the ship arrives in a port where there is a laboratory I will have them examined." Unfortunately, the responsible carrier had had the disease 11 years ago, and if all the men with a history of enteric fever had been then examined this man might have been discovered five years earlier. The strain of bacillus which this carrier is infected with seems to be a fairly virulent type, as 11 deaths are noted out of the 53 cases he was probably responsible for, and as nothing is known of a lot of the remainder, whether they died or recovered, this mortality, 20·7 per cent., is a very low estimate, though still high. The last case in the *Formidable* epidemic developed enteric on March 12th, 1914. There had been no illness suspicious of typhoid fever in her up to the time of her being lost early in the war.

The following observations were made on this carrier while in hospital. The urine was always sterile. Blood cultures were negative. The Widal reaction was positive up to a 1:150 dilution; it varied very slightly in strength. The appearance of typhoid bacilli in the stools was intermittent, three or four examinations being negative, followed by two or three positive results.

The technique used was as follows. An emulsion of fæces in normal saline was lightly centrifugalised and allowed to stand for two hours in the incubator, the upper layers of the fluid were plated out on Conradi-Drigalski's, Faucus's brilliant green, and Endo's media, and suspicious colonies proved by sugar reactions and agglutination tests. There seems to be no difference in the efficiency of these three media, all giving identically the same positive and negative results.

In 17 examinations of the fæces at intervals of about three days B. typhosus was isolated seven times.

The last point to be noted is the disposal of the patient. From the naval point of view he was not a safe man to have in any ship where any number up to 900 men live under cramped conditions. The only possible course was to invalid him out of the service, after explaining to him as carefully as possible the danger he was to others, and the necessity of avoiding having anything to do with other people's food, and the advisability of disinfecting his hands after his bowels had been open, and if possible the disinfection of his excreta. The medical officer of health of his district was informed of his address, with a view of keeping him under observation as a possible cause of typhoid cases in his district. A course of treatment with a vaccine with prolonged observations would have been tried, but unfortunately the man lives too far away to render it possible.

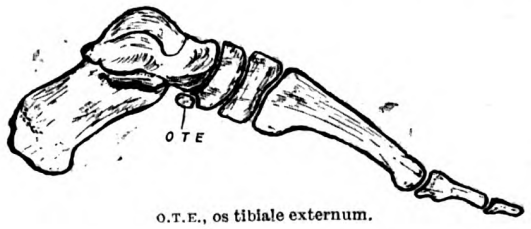
A CASE OF MARKED POST-DIPHTHERITIC PARALYSIS.

BY W. ALLEN DALEY, M.D., B.SC. LOND., D.P.H. CANTAB.,
AND
C. V. MCCORMACK, M.R.C.S., L.R.C.P. LOND., D.P.H.

AN interesting case of diphtheria was recently under our care at the Bootle Corporation Hospital. As recovery after such complete paralysis as the patient had is not very common, we think it worthy of record.

The patient, a girl aged 2½ years, was admitted on Nov. 1st, 1915. According to the history she had been quite well until the previous day, when she vomited several times and complained of sore-throat. On admission, the tonsils, the uvula, and the posterior edge of the soft palate were covered with a white, slightly hæmorrhagic membrane. The temperature was 98° F., the pulse-rate 128, and the respirations 26 per minute. No abnormality of the heart or lungs could be detected. Numerous bacilli similar to those described by Klebs and Löffler were seen in the smear from a throat swab, and their presence was confirmed by culture. The patient was given 10,000 units of antitoxin on the day of admission. On Nov. 4th the throat was cleaning, but the heart was very rapid and the first sound soft. She was given half a drachm of whisky four-hourly, which was continued until the 10th, when it was given only three times a day, and was discontinued altogether on the 14th. On Nov. 8th the heart's action was markedly feeble, and the patient was given two minim doses of liq. strychninæ hydrochloridi four-hourly; this was continued throughout the rest of her stay in hospital. On the 15th the throat was quite clean. A definite mitral systolic murmur could be heard; it became fainter until the 19th, when it was no longer present. On the 22nd the speech began to be nasal; it rapidly became more marked, and on the 25th the palate was almost immobile. On this day the heart was beating normally and the knee-jerks were brisk. About the beginning of December the first cardiac sound again became soft, and on the 8th serious vomiting occurred—always an ominous sign in such cases. Small feeds of diluted milk were given, but by this time the palatal paresis was so marked that it was impossible for the patient to take more than very small quantities of liquid by the mouth, and what was taken was not retained. For 24 hours she was fed by the rectum, and then a two-ounce feed of diluted milk was introduced into the stomach through a small rubber catheter; it was inserted directly from the mouth and not through the nose. The next day the patient took five-ounce milk feeds through the tube every three hours without any difficulty. After two days' feeding in this way the general condition had perceptibly improved, but the breathing was entirely diaphragmatic, pointing to a paralysis of the intercostal muscles. Milk feeds, strengthened by Valentine's meat extract and virol, were given regularly through the tube for over three weeks. On the 24th the patient could take single drops by the mouth and the intercostal muscles were again working; the heart was much stronger; the pupils reacted to light, but the eye movements were somewhat sluggish. By this time complete flaccid paralysis of the legs had developed; they were massaged regularly. A week later there was complete external ophthalmoplegia. On Jan. 3rd, 1915, the patient could take alternate feeds by the mouth, and on the 5th tube feeding was discontinued. She could then flex the thighs, but the extensors and flexors of the knees and ankles were still inactive. Movement of the eyes was at this time beginning to return. By the end of January everything had cleared up except for some inversion of the foot; this had disappeared by Feb. 16th, when she was discharged with no sign of paralysis anywhere and able to run about fairly well.

A CASE OF THE OS TIBIALE EXTERNUM SIMULATING FRACTURE OF THE NAVICULAR BONE.



BY C. P. G. WAKELEY, M.R.C.S., L.R.C.P. LOND.,
SURGEON, ROYAL NAVY.

THE history of this case, which may prove of interest to readers of THE LANCET, was as follows:—

A stoker, R.N.R. T., aged 23, was on duty on board his ship on Feb. 16th, when in going aft he caught his left foot in a wire hawser and fell. He was sent to the Royal Naval Hospital, South Queensferry, the next day. On examination there was found to be some swelling of the ankle-joint, and the œdema seemed to have spread up into the muscles of the calf. The foot was very tender, especially on the inner side; the arch was not destroyed in the least. On carefully examining the inner side of the foot a piece of bone could be felt in the region of the navicular bone, but no crepitus could be obtained; it was thought to be a fracture of the tuberosity of the navicular bone. On X ray examination with a screen a small round nodule of bone could be seen in the angle between the navicular bone and the talus; if the patient tried to invert the foot the fragment was slightly displaced. The right foot was screened as well, and, to my surprise, an exactly similar picture of the bones presented itself. The patient was put to bed and lotio plumbi was applied to the foot and ankle. The pain and swelling subsided in a few days, and massage to the muscles of the leg and foot was prescribed. At the end of two weeks the patient was walking about and was soon after discharged to duty. There was no sign of flat-foot and as the bone did not give rise to any painful symptoms excision was not performed.

Formerly the os tibiale externum was regarded as a sesamoid bone in the tendon of the tibialis posterior, but Waldeyer has shown that the term "tibiale externum" should include chondrifications and ossifications of the ligamentous structures and accessory slips of tendon.

The os tibiale externum is one of the most interesting of the anomalies of the tarsal bones, since it represents a first or tibial external digit, the prehallux. It lies in the medial angle between the navicular bone and head of the talus, and is usually situated in the connective tissue of the plantar calcaneo-navicular ligament and the medial process of the tendon of the musculus tibialis posterior. It does not articulate with the talus, but in rare cases it may articulate with the navicular or be connected with the latter by synostosis. It cannot, according to Waldeyer, be regarded as an isolated tuberosity of the navicular bone, because it is always somewhat smaller, although it has the form of the above-named tuberosity. According to Pfitzner,[1] who is inclined to believe that the os tibiale externum is really a sesamoid bone in the tendon of the musculus

O.T.E., os tibiale externum.

tibialis posterior, its greatest diameter is from 2·5 to 19 mm., and it occurs in males 8·3 per cent., and in females 14·9 per cent. The reasons for the preponderance of frequency in the female sex is not explained.

Manners-Smith[2] discusses the mechanical and morphological sides of the question. He regards the bone as composite in nature, formed from the following elements: (*a*) An apophysis growing from the navicular; (*b*) an epiphyseal portion (naviculare secundum) of Grüber; and (*c*) the so-called sesamoid bone in the tendon of the musculus tibialis posterior. He states that the single bone described by Pfitzner as the tibiale externum corresponds in position to the parts described above under (*b*) and (*c*).

Bardeleben[3] has demonstrated the os tibiale externum as an independent cartilaginous nodule in a 2 mm. fœtus. In many mammalia it appears as a constant skeletal structure articulating with the talus. Mouchet[4] states that when present the os tibiale externum is bilateral, and that not infrequently there are no symptoms; in other cases flat-foot occurs and pain may be partly due to that.

Medical Societies.

HUNTERIAN SOCIETY.

The Relationship of the Medical Profession to the State and the Community.

THE annual discussion of this society was held on March 22nd and April 12th, the subject of debate being the Relationship of the Medical Profession to the State and the Community. Mr. W. H. KELSON, the President of the society, was in the chair, and the proceedings were opened by Dr. F. J. SMITH, who treated the subject mainly from a historical point of view. He came to the conclusion that no serious attempt was made to give the medical profession a standing in the State until the eighteenth century, and, confining his remarks to the United Kingdom, alluded to the provisions of the Apothecaries Act, 1815, the Anatomy Act, 1832, the Medical Act, 1858, and the various Acts which have been passed in connexion with vaccination, infectious disease, and public health generally.

Mr. F. LAWSON DODD pointed out that an ever-increasing proportion of doctors would be requisitioned by the State for public health services, so that the profession must recognise that the individualist régime of medicine had almost disappeared, giving place to methods of coöperation and specialisation which were the direct outcome of scientific medicine.

Dr. T. D. LISTER was moved by Mr. Lawson Dodd's remarks to ask whether disease was still an individual thing and whether patients were to be still regarded as individuals. The science of medicine could and must evolve, he said, but the art of medicine would always remain. He regarded a State Medical Service with distrust. He considered that to improve the relations of the medical profession to the State and the community, a raising of the general standard of medical education was required, a levelling up of the numerous qualifications, and a State qualification as a necessary preliminary to any form of State Medical Service.

Dr. G. E. HASLIP said that the tendency of modern scientific medicine was more and more for combined and institutional treatment. If he were beginning again he would take a practice in a poor district with three or four partners, each a specialist in a particular line. He spoke as a student on the question of State service, but said it was absolutely essential that medical men should ascertain what they really required and organise to obtain it.

Dr. T. D. MANNING spoke as a general practitioner with some panel work and some special experience, and said that five years ago he would have agreed with Mr. Lawson Dodd, but that the profession had now tested the fruits of the interference of politicians. The first steps for the organisation of the profession must come from the inside.

At this point the discussion was adjourned until April 12th when it was resumed by Dr. H. J. CARDALE, who pointed out that the State had now accepted responsibility of the health and welfare of a great number of citizens and had thus rendered it imperative to the general practitioner to abandon his isolated position and to get into touch with modern scientific methods. The treatment of the industrial public under coöperative methods could be by the club system, the panel system, or a State Medical Service. Dismissing the first without comment, he said that the panel system was a compromise which had the merit of doing away with undercutting among members of the same profession. He could not agree with Mr. Lawson Dodd that the panel system perpetuated individualism at undue cost to the community. Whatever the progress of science, medicine would always remain an art as well as a science, and some individualism is therefore essential, but the old isolation of the general practitioner must certainly go if efficiency is to be obtained. Had it not been for the war pathological laboratories for the use of general practitioners would already have been set up in connexion with panel work. The money for these had been voted by Parliament, but it had been subsequently used for other purposes. A nursing system would also have been established by this time. It had been argued that the panel system was a system of first-aid, but with this he could not agree. Under the Insurance Act doctors treated the majority of very serious cases. The advance in science had not killed general practice; specialists were necessary, but so was the general practitioner. With regard to a State Medical Service, his objection was that it abolished the free choice of the doctor, and that he believed the public would desert the State cliniques for that reason. The State service would become a happy hunting ground for mediocrity. He considered that the medical profession ought to put forward a united constructive policy.

Dr. B. A. RICHMOND, having practised with several partners in a poor district for some years, found that the outstanding feature of such practice was that the economic position of the patients made scientific treatment an impossibility. Therefore he had welcomed the National Insurance Act as an endowment of the poor man's doctor, and though the ideals of the Act had not been fully realised, it had accomplished much. The accusation that panel practitioners were incompetent was, he said, false, the effect of the Act having been actually to weed the incompetents out, and he noted that although there were 1500 doctors on the London panel there had only been 303 complaints made in three years. They were directed against 251 doctors, 168 being substantiated. In London, he said, the personnel of the panel should be increased, and he pointed out that officials representing Friendly Societies swamped the Insurance Committees. Future developments must grow, he considered, out of the existing position. Post-graduate training for panel practitioners should be made possible and they should be attached to cliniques in their areas. Medical representation on the National Health Insurance Commission should be augmented.

After some remarks from Dr. THOMAS DUTTON, Mr. M. CURSHAM CORNER, and Dr. ETHEL BENTHAM, Dr. F. J. SMITH replied, drawing particular attention to the speeches of Dr. Cardale and Dr. Richmond. The great difficulty, said Dr. Smith, in the future would be to find enough money for adequate medical service.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF OBSTETRICS.

Myomata from a Case of Cæsarean Myomectomy.—Puerperal Eclampsia.

A MEETING of this section was held on March 24th, Dr. G. FITZGIBBON, the President, being in the chair.

Dr. M. J. GIBSON showed a specimen of Myomata from a case of Cæsarean Myomectomy. The patient was first seen nearly four years ago, when she was 32 years of age, and had been married for nearly a year. She was in very good health, and was not in any way inconvenienced by the condition of her uterus. She menstruated regularly, and there was no discomfort or pain. She did not wish to undergo an operation if she could become pregnant without doing so. The largest tumour, which was then about the size of an apple, was situated apparently in the layers of the left broad ligament and attached to the supravaginal portion of the cervix. It was consequently pointed out to her that there might be trouble during labour if she did become pregnant, and removal of the tumours was recommended. The operation was declined when she understood that there was no reason to believe that she could not become pregnant. She returned within a year for her confinement. The fibroid in the pelvis did not then seem much larger, and it was distinctly softer. It was possible to push it well out of the way and to feel the presenting part of the fœtus, which was the breech. She was anxious to avoid an operation, and the opinion was formed that the tumour would be pulled up during labour, and that it would be possible to deliver the child alive. All arrangements were made for a possible Cæsarean section, and the patient was allowed to go into labour. The labour progressed normally, and the tumour was pulled up satisfactorily. When the os was nearly fully dilated it was possible to feel the tumour above the brim, and the breech entering. The mother and child were then in good condition. About half

an hour later the fœtal heart could not be heard, and examination showed that the cord had prolapsed past the tumour through a fully dilated cervix. The child was extracted at once; there was some difficulty with the fœtal head, but not a great deal. The child was dead. The patient promised to return for the removal of the tumours, but did not do so. She returned six weeks ago for her second confinement. The pelvic tumour was now the size of a small melon, and so much in the way that it was not possible to feel the presenting part, which was the head. A Cæsarean section was performed before labour started. The child was extracted alive and the uterine incision closed. There was no difficulty in removing the tumours, two of which, including the largest, were subserous, the remainder being interstitial. There were five tumours in all. There was no more bleeding than if the uterus was not pregnant, and the extent to which the uterus could be drawn up outside the abdominal incisions made the myomectomy easier than it generally is. The removal of the largest tumour exposed the endometrium but did not open it. The cavities were closed with catgut. It was intended to allow the patient to deliver herself if she should become pregnant again, and it was submitted that Cæsarean myomectomy is the proper treatment for labour obstructed by fibroids when the uterine cavity is aseptic.

Sir WILLIAM SMYLY said that one of the most interesting questions connected with Cæsarean section was whether the uterine scar could be trusted in subsequent labours, and in that respect he considered that this case differed from the general rule, inasmuch as not only had the woman already borne a child *per vias naturales*, but the cause of the previous obstruction having been entirely removed, no unusual strain upon the uterine wall was to be expected.

Dr. T. NEILL said that he remembered a patient in the Coombe Hospital who had a Cæsarean section performed for myoma obstructing labour, and who at a subsequent labour, about 12 months afterwards, was delivered by forceps without any difficulty.

Dr. BETHEL SOLOMONS considered that Dr. Gibson was very unlucky at the first confinement. If he had attempted to deliver the child when the os was dilated before the cord prolapsed all might have been well. He (Dr. Solomons) had reported to the section a case of natural delivery after a former Cæsarean section. He had attended a case in two confinements where it had been necessary previously to remove about one-third of the uterus with myomata. With all these data, however, he thought it would be necessary to perform Cæsarean section in Dr. Gibson's case at subsequent confinements. The only other possible course to pursue would be to allow the patient to progress in labour on an operating-table and to have everything ready for an immediate Cæsarean section. He wished to know the suture material used in the case reported.

The PRESIDENT said he thought a myomectomy after Cæsarean section was better than the usual procedure of hysterectomy. He thought that the patient should be allowed to deliver herself in any consequent confinements. He held the view that when the cervix and vagina had already been dilated by the delivery of a child, and there was no obstruction, the scar in the uterus would hold, but where Cæsarean section was done on a primipara the risk of subsequent labours would be too great.

Dr. GIBSON, in reply, said he did not agree that Cæsarean section was necessary in cases of myomata, except when they were causing obstruction. He reported a case in which the scar of Cæsarean section had given way in the eighth month of a succeeding pregnancy. The incision was closed with interrupted sutures of fine silk, and there was no sepsis. He concluded that the sutures were too close, and probably drawn too tightly in this case, as when this is done he had noticed how the incision became blanched during contractions. He now employed interrupted sutures of fine silk, placed about three quarters of an inch apart, and then two continuous sutures of catgut, the first closing the muscle and the mucous membrane, the second closing the peritoneum and muscle. The silk sutures were then tied. Since then he had had no difficulty with patients who had become pregnant again, and he would allow labour to proceed in such a case when there was no longer obstruction.

Sir WILLIAM SMYLY read a paper on Some Points in Connexion with Puerperal Eclampsia, which led to an interesting debate.

Reviews and Notices of Books.

Manual of Medical Jurisprudence, Toxicology, and Public Health.

By W. G. AITCHISON ROBERTSON, M.D., D.Sc. Edin., F.R.C.P. Edin., F.R.S.E., Lecturer on Medical Jurisprudence and Public Health, School of Medicine, Royal College of Surgeons, Edinburgh. Third edition. London: A. and C. Black. 1916. Pp. 656. Price 10*s.* 6*d.*

IN our previous reviews of this book we expressed the opinion that this work contained all the information necessary for the ordinary pass examinations, and we can now endorse that view. The author has continued to include the subjects of medical jurisprudence, toxicology, and public health in one volume, and experience has shown that the manual meets with appreciation from students preparing for the final examinations; this combined treatment of the two subjects is endorsed by the fact that the subjects are taught, if not by a single lecturer, at least in a conjoint course at many universities and medical schools.

The present edition has been revised and numerous additions have been made. There are two new chapters —viz., one on medical inspection of school children and another dealing with industrial hygiene and diseases due to occupation. Further, many new illustrations have been added, several of them being original. The book is well written, the facts being stated in plain terms, and a sufficient number of illustrative cases have been quoted to add to the interest of the subject matter.

Studies in Anatomy from the Anatomical Department of the University of Birmingham.

Published by the Council of the University and edited by Professor PETER THOMPSON. Illustrated by numerous figures in the text and by 4 plates. Birmingham: Cornish Brothers. 1915. Pp. 208. Price 10*s.* net.

THE University of Birmingham is to be congratulated upon the industry and ability of the staff of its anatomical department, and not less upon the generous care of its Council in enabling good work to be produced in excellent style. The whole volume is remarkably well got up and the plates are very perfect examples of the best methods of colour reproduction. The production of such a volume in these days of war is quite noteworthy. Eight papers are included in these studies, and most of them deal with developmental problems; four of them have previously been published (three in the *Journal of Anatomy and Physiology* and one in the *Birmingham Medical Review*), and the remaining four are for the most part new. Professor Peter Thompson contributes (1) a Description of a Human Embryo, 7 mm. greatest length; and (2) the Development of the Lobus Quadratus of the Liver. Dr. Thomas Yeates has two Studies in the Embryology of the Ferret. Miss Marion Radford is represented by a paper on the Head Notochord and Pharyngeal Bursa in the Ferret and other Mammals. A paper by Mr. Lewis Graham on the Agnathic Fœtus is reprinted from the *Journal of Anatomy and Physiology*. Dr. J. Percy Good publishes a part of his Manchester M.D. thesis on an Inquiry into the Causation of Spina Bifida, and Mr. Bernard Goodwin describes a case of Partial Failure of Torsion of the Intestinal Loop. If in such a volume an individual article might be selected for especial praise, we would point to the first paper by Professor Thompson, which, accurate in details and perfect in illustrations, is a permanent record of a very interesting stage of human development.

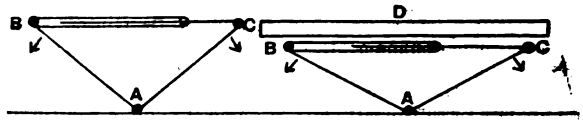
MISCELLANEOUS VOLUMES.

WE have received in the course of the last few weeks a large quantity of books of varying size and importance generally dealing with surgical nursing, bandaging, massage, and the technique of first-aid, their publication being obviously due to the large draft made by the war upon the energies of all fully trained nurses and many partially trained attendants, who are instructed to carry out special duties of particular routine. As will be seen, the books

as a whole are carefully written and calculated to be of real use to the particular persons for whom they have been designed.

Anatomy and Physiology for Training Schools and other Educational Institutions, by ELIZABETH R. BUNDY, M.D. (Fourth edition. London: J. and A. Churchill. Pp. 410. Price 8*s*. 6*d*. net), is a thoroughly good book, written by the gynæcologist to the New Jersey Training School, who has been both professor of anatomy in the Women's College of Pennsylvania and superintendent in the Connecticut Training School for Nurses.——*Bandaging*, by A. D. WHITING, M.D. (London and Philadelphia: W. B. Saunders Company. Pp. 151. Price 6*s*. net), is also of American origin, and is written by the instructor in surgery at the University of Pennsylvania. The art of bandaging is very carefully explained, and in each case the reasons for the adoption of a particu'ar bandage in a particular injury or applied to a particular region are fully explained. The book is valuable because many beginners think that the great art of bandaging is to give a pretty surface, the use of bandages to support parts and to exercise local pressures not being always explained to the beginner.——*The Triangular Bandage*, by HOWARD M. PRESTON (London: John Bale, Sons, and Danielsson. Pp. 62. Price 1*s*. net). Mr. Howard Preston is demonstrator of the practical classes at the Polytechnic, Regent-street, London, in connexion with the St. John Ambulance Association and the British Red Cross Society, and in this little work he deals with the application of the triangular bandage. The profuse illustrations and simple instructions make the book extremely suitable for the use of ambulance men and volunteer nurses, while much of the instruction could be unhesitatingly followed by Boy Scouts or Girl Guides.——*Surgical Nursing and Technique*, by C. P. CHILDE, B.A., F.R.C.S. Eng. (London: Baillière, Tindall, and Cox. Pp. xvi.+ 227. Price 3*s*. 6*d*. net), is a small book of which we expressed a favourable opinion on its first appearance seven or eight years ago, and is aimed at a far more highly instructed class. Colonel Childe has written to meet the needs of nurses who, while responsible for the technique of operative nursing, find themselves in private homes where no medical officer is resident. The book contains exactly the sort of practical information that they would require, and it may also be recommended to young house surgeons and advanced students. The book is clearly written and practical.——*A Manual for Nurses*, by SYDNEY WELHAM (London: Mills and Boon. Pp. 230. Price 1*s*. 6*d*.). This is the second edition of a handy little reference-book for nurses. The summaries of anatomy and physiology are so brief as to be of little practical use, but in dealing stenographically with medicine and surgery the author is distinctly successful. The section devoted to nursing proper contains an enumeration of the ingredients of enemata and instructions as to the preparation of poultices, blistering, painting with irritating fluids, and inunction. The book is an epitome of the kind of practical teaching which a nurse in training would receive from her superiors and learn by observation.——*Philip's Popular Mannikin*, edited by W. S. FURNEAUX (London: George Philip. Price 3*s*. 6*d*.), is a key to the model of the human body and might very well be studied in connexion with Mr. Welham's opening chapters. The information and the illustrations are excellent.——*Children's Nursing*, by C. SEYMOUR YAPP (London: Poor Law Publications, Limited. Pp. 118. Price 2*s*. 6*d*. net). Mrs. Yapp is the matron to the Poor-Law Hospital at Ashton-under-Lyne, and this book has been written for nurse probationers with a view to introducing them to a branch of nursing which naturally requires special study. The instructions are precise and properly didactic, for counsel to beginners should always be given in an authoritative manner. The book is also full of wise hints for the maintenance of cleanliness and comfort among the small patients.——*Our Baby: for Mothers and Nurses* (Bristol: John Wright and Sons. Pp. 208. Price 1*s*. 6*d*. net) is on a far lower scientific plane, none the less it introduces to the reader in simple language modern methods of rearing infants, while its appearance in a fifteenth edition proves its popularity.

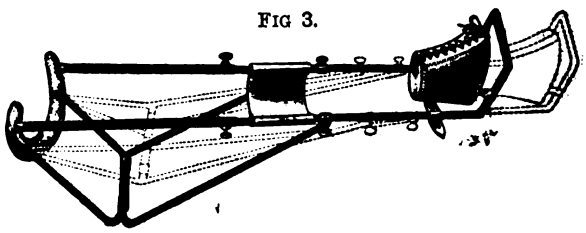
We have received the fifteenth edition of Lieutenant-Colonel R. J. BLACKHAM'S *Indian Manual of First Aid* (Bombay: G. Claridge and Co. Pp. 196. Price 1 rupee), and also Miss BLOUNT'S *First Aid at a Glance*, an adaptation from the French of a small work containing practical hints in cases of emergency (London: Good, Limited, Burleigh-street, Strand. Price 1*d*.).——*First Aid in the Laboratory and Workshop*. By ARTHUR A. ELDRIDGE, B.Sc., and H. VINCENT BRISCOE, D.Sc. (London: Edward Arnold. Pp. 32. Price 1*s*. net). Mr. Eldridge is a lecturer in chemistry at the Technical Institute, Wimbledon, and Dr. Briscoe is demonstrator in chemistry at the Imperial College of Science and Technology. Both authors, therefore, have had large experience of injuries in chemical and mechanical laboratories, and in this little book they have compiled brief and clear instructions for dealing with such injuries and accidents as are most likely to happen. The book is very brief and very sensible.



A Handbook of Massage for Beginners (Oxford Medical Publications), by L. L. DESPARD (London: Henry Frowde and Hodder and Stoughton. Pp. 247. Price 6*s*. net), has definitely been written with an eye on the existing situation. Many people are now learning the art of massage in order to help soldiers, and the book has been produced for their easy instruction, being, to a great extent, an abstraction of the author's larger book on the subject. Mr. Despard emphasises the need there will be of massage treatment for our wounded soldiers and for those discharged as unfit to serve further, and properly remarks that massage should only be carried out by those who have obtained the training of a recognised school.

New Inventions.

AUTOMATIC EXTENSION LEG SPLINT.



THE principle of this splint is that the weight of the leg is utilised as the extending force. If one imagines a triangle, A B C (Fig. 1), made of thin iron rods with the side B C extensible and hinge joints at A B C, when the triangle is resting on A it is obvious that any weight resting on B C will tend to increase the angle A and, therefore, extend the side B C (Fig. 2). Thus, if a fractured limb, D, rests on

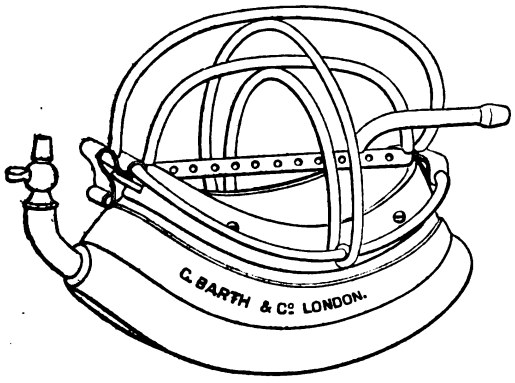
FIG. 1. FIG. 2

B C, with the two ends fixed at B and C respectively, the weight of the limb will increase the angle A and the distance B C till the muscular tension prevents further extension, and as the muscular tension is proportional to the strength and size of the muscles, and, therefore, to the weight of the leg, the amount of extension produced is approximately the amount required, and decreases automatically as the muscles waste and their tone and weight diminish. In this way over-extension, which obviously blocks the lumen of small and valuable capillaries and lymphatics both by lateral pressure and longitudinal tension, especially at the site of fracture, tends to be avoided.

FIG 3.

The splint is composed of a Thomas knee splint frame, telescopically extensible. The upper end is fixed to the leg by a 1/2 Thomas ring and it is fixed below the fracture by an anklet, bandage, or slung in the usual manner, and the

limb supported at the seat of fracture by perforated zinc or lint, and the splint is supported by two hoops of iron forming a V and connected to each other and to the splint by hinge joints. One arm of the V is connected above, the other below the seat of fracture. The weight of the leg tends to increase the angle of the V and thus extension is obtained.



The advantages of this apparatus are: (1) There is no need to move the limb or splint in slightest degree for dressing or irrigation; (2) easy access obtained to all parts of the leg; (3) no absorbent dressings are needed—any discharge can be caught in a dish underneath; (4) extension decreases as muscles waste; and (5) extension simplified in the presence of sores or cellulitis. The same splint is applicable to most fractures and any length of leg, and to lift the patient the whole thing can be made a single unit by fixing the telescopic extension by a screw, and in a similar way the height of the leg from the bed can be adjusted. If additional extension is desired, hang weights on end of splint. The chief disadvantages are that it cannot be used on a full water bed or if the knee is desired flexed.

The splint is made by Messrs. Krohne and Sesemann, Duke-street, London.

THOMAS WARRINGTON, M.R.C.S., L.R.C.P. Lond.,
Captain, R.A.M.C. (S.R.).

AN ECONOMICAL "OPEN" ETHER MASK.

THE mask for the administration of "open" ether here illustrated will, I think, be found to be economical in use and easy to hold in position. The dermatite face-piece (with its rubber air-pad) fits the face closely; consequently the eyes are not exposed to ether fumes. The outer cage is attached by a hinge to the nasal end of the face-piece.

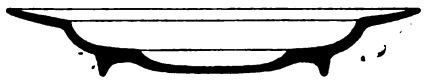
Some four to six folds of gauze are placed between the inner and outer cages and clamped down by the catch at the oral end. The outer cage affords a convenient rest, clear of the ether-soaked gauze, for the anæsthetist's thumb (or fingers) when pressing the mask in position, and when concentration of vapour is required serves to keep the overlay of towel or lint clear of the wet gauze, thus keeping it dry and the air beneath it comparatively warm. The perforated tube running from the nasal to the oral end is for the admission of oxygen or chloroform vapour from a Junker if required.

The mask has been made for me by Messrs. Barth, Poland-street.

A. BERESFORD KINGSFORD, M.D. Durh.
Upper George-street, W.

A METHOD OF IMPROVISING INTESTINAL CLAMPS.

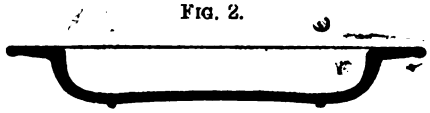
WHERE intestinal clamps are not available the following substitute will be found to answer the purpose well, and is quite easy to make and manipulate. Two equal pieces of



large, strong clock spring, from six to ten inches long, according to the length of clamp required, are covered with indiarubber tubing of a suitable size and thickness. The two pieces are bound together (A) with strong silk or silkworm gut at one end, so that when the opposite ends are brought together the springs press against one another for their whole length uniformly. The intestine, stomach, or whatever requires to be clamped (B) is brought between the two springs and held in a clamped position by nipping the other ends of the springs with an artery forceps (C) or small clamp, when it can be tied with silk or silkworm gut and the forceps removed. The pressure can be regulated by the strength of the clock spring used. For gastro-jejunostomies or intestinal anastomoses the two sets of springs can be simply tied together by leaving the silk or silkworm-gut ends long, or may be held together by artery forceps.

E. R. ROST,
Peshawar. Lieutenant-Colonel, I.M.S.

PLATES FOR ONE-ARMED USE.



I HAVE devised a couple of plates which seem to be of use to such of our sailors and soldiers as are deprived of the use of one arm. One is a soup-plate with a depression in the centre (Fig. 1), from which the last two or three

FIG. 1.

Section of soup-plate.

FIG. 2.

Section of meat- or pudding-plate.

spoonfuls of soup can be easily removed. The other is a plate for solid food which has vertical sides and an overhanging rim (Fig. 2). Against this pieces of meat or pudding can be pushed without any risk of their toppling over the edge of the plate. For convenience of commerce it has been suggested that the plates should be named, and "Unimanus" has been suggested (cf. Livy 35. 21 and 41. 21), but it seems simpler and certainly shorter to call them "manchot" plates.

The plates have been made in several styles—some as cheaply as possible—and all may be obtained from Messrs. Thomas Goode and Co., 19, South Audley-street, London, who are solely financially responsible and have kindly consented to devote rather more than 20 per cent. of the profits to the Serbian Relief Fund.

Cambridge. A. E. SHIPLEY.

THE ALEXANDRA PALACE INTERNMENT CAMP.

DURING the last year a number of reports have been current of the conditions, social and sanitary, existing in the internment camps. These have often contained conflicting statements, and we therefore take the opportunity which has been afforded us of placing on record a brief account of first-hand information concerning the best known of these camps for civilians—viz., the Alexandra Palace in this country.

The Alexandra Palace, as every Londoner knows, crowns the steep ridge of Muswell Hill, and in this healthy, wind-swept locality 2000 interned civilian aliens have succeeded to the quarters of the friendly Belgians, who were at first housed there.[1] They occupy for the most part the ground floor, where vast halls are split up for disciplinary purposes to hold battalions of 100 to 600 men. Most of them were residents in London or the Home Counties at the time the war commenced, and the numbers have been somewhat reduced by repatriation of invalids and old men.

[1] THE LANCET, Oct. 3rd, 1914, p. 867.

The halls are divided up by partitions, on the tops of which stand pot hyacinths and cactuses, suggesting at first sight some kind of flower show or exhibition. On each side of the screens are the low beds, consisting of three longitudinal planks raised an inch or two from the ground, with straw mattress, pillow, and blankets upon them. Ventilation strikes the incomer as distinctly good. The heating is carried on by means, for the most part, of hot-water pipes beneath the floor, which produce an upward current of air passing out at the louvres in the high roof and drawing in fresh air through the cracks in doors and windows without the necessity of any artificial system. The lavatory arrangements appear adequate. The original water-carriage system has been extended and washing accommodation is abundant, while douches with hot and cold water are laid on, to the use of which no restriction is applied. Each battalion of prisoners has its own particular portion of the Palace ground to exercise in, the area being marked off by wire entanglements, besides the use of the Italian garden in the Palace. At the time of our representative's visit the wind was cold in the extreme, with driving sleet, but several hundred men were pacing in the open in threes and fours around an enclosure protected from the wind at the east end of the Palace building; some were engaging in a friendly wrestling match, watched by the sentries who stood by. As closing time approached the sentries drew in, warning the men back again to their quarters.

Occupation for these men, who are all interned civilians, is, of course, purely voluntary. Several squads were engaged in removing turf and making roads, being paid by the Palace trustees for this work. Some of the aliens assist with the cleaning and housework. Large numbers are content with lying on beds idling about, or playing games. A considerable minority occupies a narrow enclosure running round the whole extent of the hall with benches on each side, on which skilled handiwork is carried out. Some are engaged in carving and fretwork inlay of no mean quality; others make wooden toys, models of boats and ships, and the like; while others are occupied more seriously in tailoring and cobbling for their comrades. All the cooking is done in the kitchens by interned civilians who command a wage for doing so. The regular ration includes 8 ounces of meat and 1½ lb. of bread per diem. The bread was noted to be wholemeal and of excellent quality, supplied by a contractor from outside. At one time some complaint was made with regard to the quality of the bread, and the contractor was changed. Those who can afford to pay may obtain food of any desired kind at the canteen; 10 per cent. of the canteen proceeds are allotted to delicacies for the remaining inmates, and especially to the occupants of the hospital. We understand that the well-to-do inmates are kindly disposed towards the others, especially in assisting them with a more varied diet. Vegetables supplied in the ordinary ration are limited to potatoes and dried beans, and no special dietary is provided for the hospital.

At the Post Office in the building parcels sent from the men's homes are examined; it is at the same time the library where English and German books can be borrowed. English newspapers circulate freely. The only German journals in evidence were of pre-war date. There is naturally an abundance of musical talent, and an orchestra of 40 instruments is formed which gives good music on Sunday afternoons. Monthly visits are allowed to the prisoners by their friends, and as these visits are spread out over the month, a constant stream of outsiders arrives each afternoon.

The hospital accommodation occupies three separate rooms at the end of the building, with a large consulting room and dispensary adjoining. Of the 35 beds in the main ward only 4 were occupied, other cases being convalescent and sitting outside in the Italian garden. Of 10 tuberculous cases only 2 had positive sputum, and these were being isolated from the rest of the men. A small room is allotted to those suffering from active forms of venereal disease. These were in the early days sent to the German hospital for salvarsan injections and are now continuing with internal mercurial treatment. The isolation hospital in the grounds is now empty; a single case of typhoid contracted before admittance and one of diphtheria have been the only serious infectious complaints; as yet influenza, if present, has occurred in very mild form. The prison in the main building is also empty, there being at the present time no disciplinary difficulties. Large glass cases in the entrance halls contain specimens of the work of prisoners, some bearing patriotic mottoes such as "Gott, Ehre, und Vaterland," others referring to the period of their detention, "Zur Erinnerung meiner Gefangenschaft," and so on.

The courtesy shown by the officials in conducting our representative all over the very large establishment and in showing us all the details contained therein is gratefully recognised.

ROYAL MEDICAL BENEVOLENT FUND.

AT the last meeting of the committee held on April 11th 26 cases were considered and £234 granted to 22 of the applicants. Two additional annuitants of £20 each were elected, to be known as the Margaret Harker-Smith Annuitants, the committee having recently received the amount of £1000 from the trustees. The following is a summary of the cases relieved:—

Widow, aged 70, of M.R.C.S. Eng. who practised at Heywood and died in 1894. Was left totally unprovided for, and earns a somewhat precarious living by acting as a day cook. Owing to age is unable to obtain permanent work. Relieved twice, £14. Voted £12 in 12 instalments.—M.R.C.S. Eng., aged 83, who had practised at Fulham. Practically blind, and has to help to support one of his son's family. Only permanent income a small pension from another society and the Old Age Pension. Previous relief five times, £34. Voted £12 in 12 instalments.—Daughter, aged 58, of L.S.A. Lond. who had practised in London and is now a pensioner of the Fund. Applicant has tried to make a living by keeping an haberdashery shop, but owing to the increased cost of commodities is unable to make it pay. Father lives with daughter. Voted £10 in two instalments, and referred to the Guild.—M.R.C.S. Eng., F.R.C.S. Edin., aged 76, married, and has practised at Lincoln and London. Owing to age and inability to get about is unable to practise. Only income a small annuity. Requires help towards the education of his youngest daughter, aged 16. Two other children, married, and unable to help. Voted £12 in 12 instalments.—Widow, aged 63, of M.R.C.S. Eng. who practised at Burton-on-Trent and died in October, 1915. Owing to long illness of husband, and three sons having joined the army, all her savings are exhausted. Receiving a little help from her sons' employers and a little from dividends. Voted £5.—Widow, aged 74, of L.R.C.P. Edin. who practised at Ross, Mon., and died in 1889. Was left totally unprovided for, and only income a pension of £15 from another society. Lives with two nieces who have to earn their own living. Voted £5 and referred to the Guild.—Widow, aged 45, of M.D. Edin. who practised at Sheffield and died in 1906. Was left unprovided for, and health is very indifferent. Has recently undergone an abdominal operation. One son, aged 16, at school and maintained by relatives. Previous relief twice, £20. Voted £10 in two instalments.—Widow, aged 59, of M.R.C.S. who practised in London and died in 1904. Applicant suffers from chronic rheumatism and general ill-health, and has no income. Previous relief 13 times, £133. Voted £15 in 12 instalments.—Widow, aged 62, of L.R.F.P.S. Glasg. who practised at Rothesay and died in 1899. Endeavours to make a living by taking in lodgers, but has not been successful of late. Suffers from rheumatism and neuritis. Relieved twice, £24. Voted £12 in 12 instalments.—Widow, aged 64, of M.R.C.S. Eng. who practised in London and died in 1914. Was left with insufficient means, and has an invalid daughter to keep. Other children only able to help slightly. Relieved twice, £24. Voted £12 in 12 instalments.—Daughter, aged 54, of M.R.C.S. Eng. who practised at Newport, Mon., and died in 1892. Is blind and health indifferent. Only income a pension of £21 from another society. Relieved five times, £60. Voted £12 in 12 instalments.—Widow, aged 46, of M.B. Edin. who practised at Strathspey and died in 1910. Was left quite unprovided for, with four children ages 9–17. Tried to make a living by keeping a boarding house, but has recently had to give it up. Only permanent income a small pension from another society. Relieved five times, £50. Voted £10 in two instalments.—Daughter, aged 67, of M.D. Edin. who practised in Lincolnshire and died in 1898. Is matron of an orphanage, but owing to lack of subscriptions her salary has been suspended. Relieved once, £5. Voted £12 in 12 instalments.—Daughter, aged 58, of M.D. Edin. who practised at Kirkdale and died in 1867. Is a dressmaker, but owing to indifferent health her business has declined, and she cannot make sufficient to meet expenses. Relieved once, £12. Voted £12 in 12 instalments.—Widow, aged 68, of M.R.C.S. Eng. who practised at Sheffield and died in 1884. Has endeavoured to make a living by teaching languages, but owing to the war her pupils have left her. Has a small pension from another society. Relieved five times, £25. Voted £12 in 12 instalments.—Daughter, aged 50, of F.R.C.S. Eng. who practised at Biggleswade and died in 1890. Suffers from chronic gastritis and epileptic fits. Only income £20 from another society. Relieved 17 times, £153. Voted £12 in 12 instalments.—Daughter, aged 60, of M.R.C.S. Eng. who practised at Peckham and died in 1886. Owing to the weak state of her health she is unable to undertake any permanent work. Lives with sister, who has to earn her own living and is unable to help applicant. Relieved 18 times, £209. Voted £12 in 12 instalments.—Widow, aged 58, of M.R.C.S. Eng. who practised at Sydney, N.S.W., and died in 1901. Has no income, but receives occasional help from friends. Has a house in the country which she cannot let owing to its bad condition. Has one daughter, a professional singer, but owing to the war she cannot obtain any engagements. Relieved twice, £20. Voted £10 in two instalments.—Widow, aged 68, of M.R.C.S. Eng. who practised in London and died in 1898. Endeavours to make a living by taking in boarders, but has been unsuccessful of late owing to ill-health, applicant suffering from a cancer. Has five daughters, all unable to help. Relieved 17 times, £205. Voted £12 in two instalments through the Guild.—Widow, aged 53, of M.B. Aberd. who practised in Warwickshire and Australia and died in 1909. Was left unprovided for, and only help a little from relatives. Has three children, ages 29 to 31, but none able to help. Applicant is suffering from asthma and heart trouble. Relieved seven times, £73. Voted £12 in 12 instalments.

Subscriptions may be sent to the honorary treasurer, Dr. Samuel West, at 11, Chandos-street, Cavendish-square, London, W.

THE LANCET.

LONDON: SATURDAY, APRIL 29, 1916.

The Registrar-General's Annual Report for 1914.

IN a prefatory address to the President of the Local Government Board Mr. BERNARD MALLET, the Registrar-General, expresses regret that his endeavours to expedite the publication of his annual report for 1914 have been defeated by the exigencies of war. He tells us that military requirements have led to the imposition of new and unaccustomed duties on his department, as well as to the serious depletion of his staff by the enrolment of many of its expert members. Out of 116 men in this Government department not fewer than 62 are already serving with the colours, whilst 12 have been detached for war service in other departments. Altogether 64 per cent. of the men of military age have been withdrawn from the General Register Office, and the residue includes several men who have been refused by the military authorities for medical reasons. These losses have been met by the closing down of all work not immediately required, by overtime employment, and by the substitution of female clerks for male. In spite of increasing pressure on the department occasioned by the war, it is satisfactory to hear that in certain directions material improvement has been achieved in the period under review. The Registrar-General has taken pains to minimise the inconvenience of delay in the issue of his complete report by accelerating the publication of the "Annual Summary" for the same period—a document which will be found to convey important information not otherwise available to those responsible for the preservation of the public health. For the information of those unfamiliar with this publication, it may be useful to mention that it is now published within about three months of the close of the year to which it relates. The accuracy of the provisional numbers there given depends on returns by the local registrars, who are mainly laymen. But in the preparation of the official report, which is largely a medical function, these numbers are revised by comparison with the statutory registers deposited in Somerset House; they are analysed in greater detail, as well as, presumably, with greater accuracy, than had been possible in the production of the earlier publication. For these reasons it is obvious that the summary can never be accepted as a substitute for the elaborate official report.

With few exceptions the vital statistics of 1914 may be considered satisfactory. The marriage-rate, like that of 1912 and 1913, showed a substantial rise on the average for 1908–11, and the provisional figures for 1915 indicate a further considerable rise. In order to compensate as far as possible for the casualties of war it is necessary to maintain at the highest standard the constitution of the general population; and in this relation the persistent decline in English fertility demands scientific consideration. In 1914 a further falling off in the fertility of English mothers is recorded. In 1876 the rate of birth attained its highest point—namely, 36·3 per 1000 of the population—since which date it has fallen, with few exceptions, continuously from year to year. In the year 1914 it was only 23·8, being the lowest rate on record; it was below the average rate for the last complete decennium by not less than 3·4 per 1000, a very serious decline. The general mortality of 1914 in England and Wales was 14·0 per 1000 living, without distinction of age or sex; it was below the decennial average by 0·7 per 1000. Except in the years of childhood males experience a higher mortality than females, although the excess is very unevenly distributed over the country. The fall in mortality has been rapid since 1891–5, when it stood at 18·5 per 1000. Up to the age of 35 for males and of 45 for females the mortality of 1914 at each period was only half that recorded 50 years ago, but after these ages the fall was only slight. Of the total deaths 17·8 per cent. were those of infants in their first year; their rate of mortality therefore was equal to 105 per 1000 births. Infantile mortality is ordinarily higher in the town than in the country, but the infant mortality of London, the centre of the largest urban population in existence, continues lower than that of the country at large. In view of its constancy from year to year the geographical variation of infant mortality in England and Wales is remarkable. In each sex, and in every class of area, the rate continues highest in the north of England and lowest in the south, the position of the Midlands being intermediate. Even the rural districts of the north record a higher rate than that of the metropolis, the excess being greater in the male sex. Illegitimacy is known to exercise a powerful influence on infant life, and in 1914, as in previous years, the mortality of illegitimate infants was about twice as high as that of children born in wedlock. The excess was highest at ages under three months and least in the later months of the first year of life.

Respecting the mortality from the common infectious diseases the Registrar-General writes briefly, probably because detailed information respecting their incidence and fatality has already appeared in the annual summary which was published in April, 1915. The death-rates from these diseases, with the single exception of diphtheria, were below the average. Diphtheria was responsible for greater destruction of life than usual, and in its regular tendency to excessive prevalence in the same area from year to year this disease strongly resembles enteric fever. The loss of life due to tuberculosis in 1914, although somewhat greater than in the preceding year, was below the average in the latest quinquennium by nearly 14 per cent. The fall in mortality was shared almost equally by both sexes, but the rate among

males continues to exceed that of females by about one-third. As in former years the excess was far greater in the chief towns than elsewhere, being 66 per cent. in London against 4 per cent. in rural England. More than three-quarters of the total mortality from tuberculosis was due to the pulmonary form of that infection, which was somewhat less fatal than the average. Among other forms, tuberculous meningitis caused a lower mortality than in any previous year; it now amounts to not more than one-third of the rate prevailing 60 years ago. The mortality from tuberculous peritonitis was lower than in any previous year except 1912; the rate has been rapidly falling for the last 30 years, and now averages only one-third of its former amount. There is no abatement of the suffering and fatality due to malignant disease in its various forms. In 1914 there was again an increase in cancer mortality among males, especially those at advanced ages; there was also a slight increase among females, especially those above the seventy-fifth year of life. Very elaborate analysis continues to be made of the mortality from this terrible disease, and no pains have been spared by the Imperial Cancer Research Fund to improve our knowledge of its nature. We notice with pleasure the Registrar-General's acknowledgment of the assistance he has received from medical officers of health in the compilation of his report, and especially for their coöperation in securing accurate transfer of deaths, with the object of improving the vital statistics of our country.

The War and Epidemic Diseases in Galicia.

THE miseries attending military operations in the eastern war-zone have been exemplified by what has occurred during 1915 in the Austrian province of Galicia, which has a large industrial population, and where, in addition to destruction of property and the shortage of food supplies, certain dangerous diseases have been epidemic. Many villages and farmhouses have been burnt to the ground, the cultivated fields have been devastated and the crops destroyed, business premises have been demolished and many of the inhabitants have fled into the already overcrowded towns where provisions are scarce and housing is inadequate; to crown all, cholera, exanthematic typhus, and small-pox have been widely prevalent. The Austrians themselves have estimated the permanent damage done to property in Galicia up to the end of 1915 at more than £80,000,000.

Although the usual sources of information as to infectious diseases in Austria are closed, numerous reports published in Vienna filter through neutral countries to England, and from these accounts it appears that cholera has been prevalent in Galicia during the summer months of the past year, subsiding with the advent of the cold weather. It is, however, probable that there will be a recrudescence of the epidemic when the seasonal conditions become again more favourable for its spread. Approximately about 30,000 persons were attacked by cholera in the province during the year 1915, but the number of deaths has not yet been stated. The majority of the sufferers belonged to the civil population, the military escaping, probably as a result of the anti-cholera inoculations carried out before the epidemic had developed. It is surmised that the cholera infection was introduced into Galicia from Russia. It is a well-known fact that exanthematic typhus is endemic in this province, about 2000 cases on an average being reported annually. But in 1915 the number of attacks rose to 9000, increased in the first two months of 1916 by 2354 more cases, making a total of 11,354. The fatality of the disease has not been reported, but it is probable that it was not less than 20 per cent. As with cholera so with typhus, the victims were chiefly among the civil population, famine, overcrowding, vermin infestation, and general misery assisting in the production of the epidemic. Small-pox has been prevalent in Galicia almost throughout the whole of 1915, but it assumed more serious proportions at the beginning of 1916. Up to the end of the month of February of the present year about 32,000 persons had been attacked among the civil population with whom vaccination is generally neglected; the troops were not seriously affected, vaccination and re-vaccination being performed at the beginning of the military service of each recruit. The number of fatal cases of small-pox which occurred in Galicia during 1915 has not yet been published, but the prevailing conditions are such as to be likely to enhance the virulence of any current infection and increase its fatality. As showing the proportions which this epidemic is now assuming, it may be mentioned that in January and February of the present year the number of small-pox cases reported to the authorities amounted to nearly 12,000.

From these facts it appears that apart from death and disablement of soldiers on the battle-fields of Galicia, many of the inhabitants of the province have lost their homes and sources of employment through the so-called "military necessities," and many of them are suffering from famine and other miseries, as well as being ravaged by such dangerous epidemic diseases as cholera, typhus, and small-pox, which history has shown often follow like vultures in the track of armies in the field.

DONATIONS AND BEQUESTS.—By the will of the late Mrs. Harriet Harris, of Hackney, who left estate of the gross value of £10,428, the Queen's Hospital for Children, Hackney, the King's Nursing Home, and the Home and School for the Blind, Upper Clapton, will each receive a fifth of the residue after a few legacies and bequests have been made.—The late Dr. Abraham Cross Godfrey, of Broom Hill, Dripsy, Co. Cork, has left £1000 each to the South Hants Hospital and the South Infirmary, Cork.

THE CHADWICK PUBLIC LECTURES.—The next course of Chadwick Public Lectures will begin on Saturday, May 6th, when Miss Lilian Barker, lady superintendent at Woolwich Arsenal, will take for her subject Housewifery in the Army, Camp Kitchen, Economy, and the Effects and Defects of Munition Work for Women. The lecture will be delivered at Bedford College, and Sir William Collins will preside.

Annotations.

"Ne quid nimis."

LUNACY IN EGYPT.

Dr. J. Warnock has now issued his annual report,[1] giving a brief account of work done. He has been appointed consultant to the British army in Egypt and he has had to make special arrangements for the treatment of British soldiers who were mentally affected. The report gives evidence of steady progressive work and shows the persistent and untiring energy of Dr. Warnock, who has been obliged to do so much extra work with a reduced staff. He points out that the admissions for the year have been fewer and he is inclined to think that the chief dangerous vagabond lunatics are now under care. The admissions once more exceed the accommodation by 467 patients, and again a large number of uncured patients, 487, have been discharged to the care of their friends. Dr. Warnock reports that his admissions of fresh cases for the year in fact were 1036; this is a larger admission list than that of any British asylum. One hundred military mental cases were treated during 1915, and the tables as to forms of insanity and of the attributed causes are interesting. The majority were depressed and melancholic, the Indian contingent providing a larger proportion of these. As usual there was a considerable number of patients admitted who had suffered from violence, and 16 employees were injured by aggressive patients. Some patients were admitted as voluntary boarders, and this appears to point clearly to a better understanding among Egyptians of the object of the asylum. Lectures and demonstrations were given not only to medical students, but interesting medico-legal cases were demonstrated to the law students, and Dr. Warnock acted as examiner in forensic medicine at the School of Medicine. Of late years the work has been increased and made more trying by the reception of criminals supposed to be insane. It is a remarkable fact that of 33 male and 4 female convicted prisoners sent for observation 19 males and 1 female proved to be sane and were returned to prison. Of 50 males and 9 female accused persons sent for examination 15 males and 1 female were found not insane. An interesting table gives the forms of insanity associated with the crimes. In this it is noteworthy that the pellagrous insane seem to tend to murderous violence. The recovery-rate is small, but this is partly accounted for by the discharge of uncured but improving cases to make room for more urgent ones. Of the 873 admissions hashish provided 47, while the pellagrous insane were 135 and the general paralytics were 57. Of the hashish patients only one was a woman, of the pellagrous 75 males and 60 females, and of the general paralytics 11—that is, nearly 25 per cent.—were women. The report has been prepared with the greatest possible care. The tables exhibit clearly the chief points as to causation of the disease and the causes of death. A good proportion of post-mortem examinations were made, and a skilled pathologist—a young Egyptian—did excellent coarse pathological as well as microscopical work. Dysentery was again common and was treated with Dr. M. A. Ruffer's antidysenteric serum; 68 cases recovered and 18 died. Both typhoid and typhus fevers occurred in the asylum with some deaths. Blood examinations were made and examinations of excretions were also carried out. Preparations have been made of the nervous tissues of pellagrous patients, and later reports will be made. Wassermann tests were carried out at the Laboratory of Public Health. Of 223 cases suffering from various forms of insanity 94 gave a positive reaction, but the full report on this line of work will be developed later. There is accompanying Dr. Warnock's report a shorter report of the work done at the sister institution at Khanka. The present accommodation there is for 400, but 700 have been received at a time. The usual tables of causation, forms of disease, and modes of treatment are given, and very complete information as to the uses made by the full electrical plant for the various needs of the asylum. It is a great difficulty that there are no convenient roads from Cairo to Khanka, but no doubt this will be met and gradually, under Dr. H. W. Dudgeon, a large asylum will be carried on under more suitable conditions than could prevail in the old buildings. The new buildings are specially arranged for their object, whereas the parent institution was adapted from an old palace. The future of Egyptian lunacy is hopeful, and when peace is restored progress will be more rapid.

BULLET IN THE RIGHT AURICLE; OPERATION; SURVIVAL FOR TWO DAYS.

DURING the present war wounds of the heart have been fairly frequent, and in some cases the lack of serious results has been a matter of considerable surprise. The diagnosis when the bullet remains in the heart is rendered certain by the X rays. Usually the missile is only a small fragment, and it is the ventricle which is damaged. But in the case to be recorded it was the auricle which received the bullet, a much graver condition. The soldier was wounded on May 14th, 1915, when 1500 metres from the German trenches, the bullet entering the right subclavicular region. He immediately felt a violent pain of a pricking character in the heart, and then fainted away. For some days he lay in an extremely grave condition, with occasional hæmoptysis. There was severe retrosternal pain lasting continuously for hours and accompanied by intense headache. Gradually he improved, and by the end of July could get about, but any effort was likely to cause faintness and urgent dyspnœa. The entry wound had healed; the retrosternal pain, however, still persisted. On Sept. 27th examination showed no demonstrable changes in the heart; there was no abnormal pulsation; the pulse was variable in rate, usually at 60, but on slight movement rising to 100. There were diminished breath sounds at the base of the right lung. X rays demonstrated the bullet resting definitely in the right auricle, a skiagram showing this clearly. The scar of the wound was in the third right intercostal space, two fingers' distance from the right edge of the sternum. On Oct. 13th the patient developed acute myocarditis. There were pyrexia, some evidence of pericarditis, and severe cardiac pain. The area of cardiac dullness was increased and the rhythm disturbed, long pauses occurring. On Nov. 1st the patient was better, and on the 9th it was decided to operate and remove, if possible, the bullet. The central mass of the sternum was removed, with the third, fourth, and fifth costal cartilages on either side. The considerable hæmorrhage from branches of the mammary

artery was controlled before the pericardium was opened. Numerous pleural adhesions existed on the right side. An incision 7 to 8 cm. long was made. The pericardium was found to be adherent. With the finger the adhesions could be separated without difficulty over the surface of the ventricle, but over the auricular surface they were of some density and could not easily be removed. It was then easy to feel the bullet, the point of which was situated just above the opening of the inferior vena cava in the wall of the auricle, and enclosed or ensheathed in a hard mass of tissue. At this stage the general condition of the patient occasioned much alarm. There was intense pallor and the pulse became almost imperceptible. The heart also showed irregular tumultuous movements. The organ was carefully moved over a little towards the left, which rendered the site of the bullet more accessible, and a pair of forceps was placed superficially to prevent hæmorrhage when the bullet should be extricated. Unfortunately the tissues in this region were friable on account of the adhesions; suddenly the auricle ruptured, and a startling welling up of black blood immediately followed. The operator at once placed the left forefinger into the breach, and after a time managed to unite the edges with a small covered clamp. The bullet was then quickly removed with a bistoury and sutures were inserted. Tampons were placed in the neighbourhood of the lower angle of the sternum and an obturator construction closed up the thoracic anterior wall. The operation lasted 50 minutes. With the closing of the pericardium the general condition of the patient improved, and the pulse became regular at 120, respiration 25. For the rest of the day there were pains in the chest. At night the pulse was 140; no faintness. Transfusion of blood was carried out to make up for the loss when the auricle ruptured, estimated at about 200 grammes. The pulse slowed a little and the patient improved somewhat. The following night was also good, but the thoracic pains continued. Hyperglucose serum was given; the pulse, however, accelerated. The next day, Nov. 11th, the temperature rose, and later the patient died. The remarkable fact brought out in the necropsy was the vigorous fibrosis which had surrounded the bullet, resembling a "veritable fibroma." The capsule surrounding the bullet averaged 1½ centimetres in thickness. Only by this pathological process could the bullet, which, weighing 8 grammes, was 28 millimetres long and 8 millimetres in diameter, be held in the auricular wall, which normally is only 2 to 3 millimetres in thickness. A full account of the case has been detailed by Dr. Couteaud and Dr. Bellot in the *Revue de Chirurgie*. It will be interesting to see whether more success may follow similar operations, which must demand a maximum of manipulative dexterity and confidence on the part of the operator.

NON-FATAL FRACTURE OF THE AXIS.

Dr. F. W. O'Brien has recorded in the *Boston Medical and Surgical Journal* a case of the rare condition of non-fatal fracture of the axis. A boy, aged 7 years, was admitted into hospital with a history of having fallen from a tree five days before and striking the ground on his back. He complained that he could not move his head without pain. He adapted himself to this condition by supporting his jaw along the ramus with his hand. In this way he was able to turn his head more freely. The pupillary and other reflexes were normal and there was no paralysis or disturbance of sensibility. Pressure over the second and third cervical vertebræ was painful. Radiography showed a complete fracture of the laminæ of the axis, and an orthopædic support was applied. After five weeks this was removed, and radiography showed such excellent union that an observer might doubt that there had been any fracture. At the time of the report the child was playing about as if nothing had happened. Mixter and Osgood, in reviewing the literature of "Traumatic Lesions of the Axis and Atlas,"[1] have called attention to the large amount of room for the spinal cord in this region, which may account for the absence of symptoms in certain cases of cervical injuries. In injuries of the axis the mortality seems to depend on involvement of the odontoid process. In 6 out of 8 fatal cases recorded by Mr. E. M. Corner the odontoid process was broken, while in 10 non-fatal cases fracture of the odontoid process occurred but once.

INFLUENCE OF PITUITARY FEEDING UPON GROWTH AND SEXUAL DEVELOPMENT.

THE clinical evidence of the effect of the pituitary gland on growth and sexual development is well known, but experimental feeding with and injection of pituitary extracts has given contradictory results. Thus Crowe, Cushing, and Homans found that subcutaneous injections of extracts of the whole gland or of the posterior lobe were apt to produce emaciation. On the other hand, Caselli could find no effect. Schäfer fed young rats with the anterior lobe, which seemed to produce increased growth, but more recent observers reported negative results. Bohenroth is the only writer who investigated the effect on the genital system. He found that hypodermic injections of pituitrin produced in rats premature and extensive development of the genital system, particularly of the testis and sexual over-activity, but in young dogs the results were negative. This may have been due to a difference in activity of the extracts used or to incorrect dosage. In the *Johns Hopkins Hospital Bulletin* Dr. E. Goetsch has reported an important and careful investigation of the subject. Two young bitches of the same litter were taken; one was fed daily with half a gramme of the dried extract of the anterior lobe of the pituitary gland, and the other was used as a control. After seven months the animals were killed. The ovaries of the former contained numerous corpora lutea and albicantia, while those of the control contained simply unripe Graafian follicles. An extensive series of experiments was then made with young rats. When fed with excessive doses (0·1 gramme daily) of the dried extract of both anterior and posterior lobes failure to gain weight, loss of appetite, increased peristalsis, mild enteritis, and nervous manifestations, such as muscular tremors and weakness of the hind limbs, were produced. The latter symptoms were due to the posterior lobe element, for they could be produced by administering an extract of this lobe, but not of the anterior lobe. The ovaries, tubes, and uterus of animals fed with extract of the whole gland were larger and more vascular than in controls and the ovaries reached sexual maturity from one to two months before normal. In males premature growth and development of the testes, with spermatogenesis, was produced. Feeding with anterior lobe extract resulted in increased weight and more vigorous body growth and earlier

[1] American Journal of Orthopedics, February, 1910.

genital development. The fur was harsher and thicker. Feeding with the posterior lobe did not stimulate growth or sexual development; indeed, it had a retarding influence on the latter. These results explain why in acromegaly, now believed to be due to over-activity of the anterior lobe consequent on adenomatous hyperplasia, there is in the early stage increased sexual activity and in the late stage, with pituitary involution, disappearance of the sexual function and atrophy and degeneration of the sexual glands. The view put forward by Biedl that deficiency of the secretion of the posterior lobe causes genital hypoplasia seems incorrect. This deficiency causes a tendency to the deposition of fat and increased carbohydrate tolerance, which can be favourably influenced by administration of posterior lobe extract. Cases of pituitary disease in which symptoms of sexual failure, such as amenorrhœa and impotence, have been favourably influenced by administration of pituitary extract by the mouth have been recorded by Cushing. This treatment also seems indicated in conditions of genital aplasia and adiposity and in circumstances referable to ductless glands other than the pituitary.

REFORM AND DELAY.

To find Dr. F. J. Waldo, the coroner for Southwark, as well as for the City of London, calling the attention of a jury to the insanitary phenomena observable in the "Tabard-street area," carries us back in memory many years before the war, when there was more leisure and more money for the removal of such abuses than is likely to be the case for some time to come. At the inquest referred to it was proved that a woman had died as the result of heart failure from an attack of bronchial catarrh, and there was evidence that the roof leaked, the floors were rotten, and the paper on the walls was falling off from the damp. A medical witness summed up the condition of the room, for which a rent of 6*s*. per week was paid, by saying that "it was not necessary to hold an umbrella over the bed where the deceased slept, but the rain came in everywhere else." In these circumstances death consequent upon bronchial catarrh was ascribed with literal accuracy to "Natural causes," but a rider, added to its verdict by the jury, which asked that the houses where the death took place should be condemned, was prompted, no doubt, by the feeling that such deaths may be natural but are not unavoidable. As a matter of fact the houses, we understand, had been already condemned as unfit for habitation some years ago, and they were cleared of their inhabitants, but their demolition was delayed and tenants have again been allowed to occupy them. If their condition to any general extent is such as was described at the inquest, it is to be regretted that their existence was not cut short at an earlier date. Promptitude of action is frequently a cheaper course than delay, and there must be many examples of expenditure postponed with increased cost as its result. The housing of the working classes of London was recognised as a difficult problem long before the close of the nineteenth century, and although cheaper locomotion has provided a solution to a certain extent, higher land values and more costly labour have made us wish that the fathers and grandfathers of the present generation had done more towards settling a question which was raised and shelved in their day. And, alas, when peace comes, this and similar matters of extreme social urgency may find themselves relegated still further into the background by circumstances arising out of the war and by lack of funds consequent upon it. And where pecuniary considerations are not involved time and opportunity for legislation may not be easily secured. Reform connected with the registration of deaths and with the holding of inquests has long been delayed. The report of the Royal Commission on the Poor-law has borne no such fruit as was expected to result when the Commission closed its labours. Quacks and nostrum-vendors are still carrying on a profitable trade at the expense of the public and to the detriment of the health of their clients. It is easy to say that there are matters of more instant importance than these, and that other questions will arise demanding settlement when the affairs of the nation are nearer to resuming their normal course. It may be admitted that matters of merely comparative urgency must often stand aside for others more insistent in their demand for attention. It would seem, however, that in domestic legislation and in public health administration, as in other affairs, arrears are more easily accumulated than got rid of, and that postponement when once it has taken place is liable to be repeated or prolonged. The allowing of the "Tabard-street area" to become inhabited again is a good example of dangerous procrastination.

TUBERCULOSIS IN THE NETHERLANDS.

TEN years ago the Dutch Association for the Promotion of Science set up a committee of medical men to make a statistical investigation into the pathogenesis and spread of tuberculosis in Holland. A table of 53 leading questions was drawn up, with numerous subdivisions, to illuminate the points at issue; forms containing these questions were issued to 261 medical men in Holland, who were asked to fill in a form for each of their tuberculous patients and to return it to the commission. After the lapse of much time 92 medical men sent in returns dealing with 1510 tuberculous patients. The commission has worked up these statistics, and has recently published an account of them, together with the general conclusions to which they lead.[1] Over 92 per cent. of the patients were suffering from tuberculosis of the lungs alone; only 47 patients had tuberculosis of other parts of the body alone. Almost exactly half were males. Summing up the results of their investigation, the commission remarks that nothing in the nature of certainty can attach to their conclusions, owing to the nature of the material on which they are based and the variety of the facts concerned in the acquisition of a tuberculous infection. They believe that tuberculosis most commonly appears between the ages of 14 and 40; more than half the patients take notice of the infection and seek medical advice within a year of its occurrence. The acute infections appear to play an important part in opening up the way for tuberculosis, more particularly influenza; alcoholism, grief, and anxiety seem to have no influence as predisposing causes. The small number of the patients who gave a history of recovery from tuberculosis of some part of the body in their early years indicates that a tuberculous infection is apt to produce a certain degree of immunity to the disease. Many of the patients exhibited the scrofulous diathesis

[1] Nederl. Tijdschr. v. Geneesk., Amsterdam, 1916, vol. i., pp. 601-644.

(38 per cent. of 887 cases), and many of them were members of large families. As regards childhood, tuberculosis is commoner at the beginning and end of this period of life; in the case of girls, going out into service and hard work increase the liability to tuberculosis. So far as men are concerned, occupations like those of printers and workers in wood, cork, straw, and metal, increase the liability to tuberculosis; agricultural labourers, both men and women, are comparatively rarely infected. Domestic service seems to be particularly unfavourable in the case of women. Importance is attached to the home circumstances; tuberculosis is commoner in houses that get no sunlight, and in persons who have slept two or more in one room or one bed. The actual source of infection was undiscovered in 488 of the 1510 cases investigated; in 823 (or 54·5 per cent.) the infection was acquired beneath the parental roof, and in the remaining 199 patients the source was said to be the husband or wife, fellow workers, friends, servants, boarders, persons nursed, or, in 30 cases, residence in an infected house. In 604 married tuberculous persons the spouse was certainly tuberculous in 65 instances and possibly tuberculous in 12 more. The commission states that no conclusion as to the importance of heredity in the acquisition of tuberculosis can be drawn from their figures; but they are of the opinion that it is a factor of some significance.

THE PATHOGENESIS OF ACROMEGALY.

SINCE Pierre Marie in 1886 called attention to the peculiar and interesting dystrophy which he named acromegaly, numerous cases of this striking morbid entity have been described, but although in their general aspect and evolution such cases more or less resemble each other, clinical investigation of each particular case reveals some peculiarity or detail worthy of special examination. Professor Massalongo and Dr. Piazza, in the medical section of *Il Policlinico*, February and March, 1916, publish a case which lends support to the view that acromegaly, which has its primary origin in hyperfunction of the pituitary gland, is often complicated by contemporary or successive phenomena dependent on functional or organic change in other glands with internal secretion; such complications are deserving of discussion and interpretation as to whether they should be considered invariable or exceptional, independent or accidental occurrences, or subordinate and necessary. In the case published by these observers, ocular disturbances, modification of the field of vision with marked changes shown by radiography, left no doubt as to the existence of a pituitary lesion. Other facts, however, made it impossible to exclude the presence of symptoms dependent on simultaneous changes in other endocrinous glands, especially of the thyroid and genital glands. In fact, the case might be taken as an example of a thyro-genito-pituitary syndrome to which various authors, chiefly French, have drawn attention in recent years. The implication of the other glands except the pituitary, whether it represents an independent and accidental occurrence or one subordinate and necessary, is not, however, equivalent to saying that acromegaly is a pluri-glandular syndrome. Changes in these glands do not signify their participation in the pathological process of acromegaly, but, according to these observers, are capable of an entirely different explanation, which is that the endocrinic system constitutes an organo-functional whole, whose constituent elements are physiologically in such intimate connexion that one of them cannot undergo any change without a reaction taking place in the others.

THE SUPPLY OF PETROL TO MEDICAL PRACTITIONERS.

THE President of the Board of Trade has appointed a committee, consisting of Mr. Oliver Bury (chairman), Mr. A. E. Bowen, Sir John Prescott Hewett, G.C.S.I., and Mr. P. G. L. Webb, to control the supply and distribution of petrol, and to consider what measures are necessary in the national interest—(1) To ensure that adequate supplies of petrol shall be available for the purposes of the war and for other essential needs; and (2) with the above object, to regulate the use of petrol for other purposes in the United Kingdom during the period of the war; and, subject to the direction of the Board of Trade, to give executive effect to the measures decided upon. Mr. H. W. Cole, of the Board of Trade, will act as secretary to the Committee, whose offices will be at 29, Abingdon-street, Westminster, S.W. The Committee will not consider individual applications for supplies of petrol, or deal with correspondence relating thereto; but if the medical man is to receive that adequate supply which is absolutely necessary to enable him to carry out his professional duties, it should be somebody's business to give attention to his requirements. A few days ago, in one of the daily papers, a medical practitioner complained of inability to get petrol for over a fortnight, stating that he was "responsible for medical attendance on over 2000 people engaged directly or indirectly on munition work." If such instances as these are allowed to multiply, the health of the community will speedily suffer. A form has been issued to medical men by the National Health Insurance Commission, on which they are requested to state their estimated need of petrol, but we learn that some 7000 practitioners have not yet made a return as to their requirements. We think this is regrettable. The question of the supply of petrol to the medical profession is one which will be best dealt with by an organised body, and the National Health Insurance Commission should be able to influence the Government to ensure that medical men generally shall have the first consideration, so far as private users are concerned.

STREPTOCOCCAL PUERPERAL FEVER IN THE ANGLO-EGYPTIAN SUDAN.

IN an interesting paper in a recent issue of the *Journal of Tropical Medicine and Hygiene* Dr. Albert Chalmers, director of the Wellcome Tropical Research Laboratories, Khartoum, and Dr. Salim Atiyah, medical officer in charge of the Omdurman Civil Hospital, discuss the incidence of streptococcal puerperal fever in the tropics, with special reference to the Anglo-Egyptian Sudan. The attention of these observers was called to the subject by the occurrence of several cases in Khartoum and Omdurman associated with the presence of a streptococcus in the uterine discharges. The question of childbirth among non-civilised races is considered, and it appears that there is some agreement of opinion that labour is easier among them than among those that are more civilised. The reason advanced

for this is that pregnancy in the former generally takes place at an earlier age than in the latter, and that the hard life and spare diet common in the non-civilised races keep the young women thinner, a condition which is favourable to a quick and easy labour. Some experts also assert that the head of the child in the uncivilised races is smaller than in the civilised, and that on an average the child of the uncivilised woman weighs at birth about a pound less than that of a civilised mother. Childbirth in these circumstances is often a simple physiological process among savage races, and therefore less likely to be complicated by puerperal infection. According to Dr. Chalmers and Dr. Atiyah, among the semi-civilised Arabs and Sudanese of Kordofan and other parts of the Sudan every young girl on attaining the age of 5 or 6 years undergoes one or other of the two forms of so-called circumcision, the milder operation consisting of the removal of the clitoris and labia minora, while the more severe, or "Old Egyptian circumcision," entails some additional cruelty in the removal of the upper two-thirds of the labia majora. The result of these operations is the formation of scar tissue and contraction of the orifice of the vagina, necessitating enlargement by means of a razor at the time of marriage, and again at the birth of a child, otherwise it would be difficult for the head to emerge from the outlet at the moment of delivery. The enlarged orifice is again closed partially after the child is born, and consequently incision with the razor is required at each succeeding labour. These wounds naturally offer opportunities for septic infection, and streptococci and other organisms have been found in the vaginal discharges. After reviewing the literature of the subject, the writers refer to the various forms of the genus streptococcus, and call attention to two closely allied streptococci—S. salivarius and S. bovis—both of which are known to occur in human saliva and in cow-dung, S. bovis being also found in human fæces. Cow-dung, it appears, is used as a remedy for various ailments in the Sudan, sometimes in the form of a poultice applied to the painful part of the body, including the external genitals of pregnant women. Moreover, a cow-dung wash is used on the floor and walls of rooms to keep away biting insects, and in Khartoum and Omdurman cow-dung is employed as a wash for the top of ovens and also for the walls of outhouses where grain is stored. When this wash dries it forms dust, which may be wafted about, the streptococci contained in it being known to be resistant to the effects of desiccation. It is possible therefore for this streptococcal dust to contaminate the hands of attendants upon parturient women and thus lead to their infection. Dr. Chalmers and Dr. Atiyah state that they suspect that the vagina and later the uterus become infected by bovine fæcal streptococci, conveyed either through the agency of the patient's own fæces to her genitals, or by dust on the hands of the attendants or on the instruments which may be employed. In their opinion the real protection against this form of infection is the use of antiseptic vaginal douches before and after delivery, associated with antiseptic intra-uterine irrigation in cases in which it has been necessary to introduce the hand or an instrument into the uterine cavity. Every antiseptic precaution must, they say, be more forcibly insisted upon in the tropics than in more temperate climates.

THE FRENCH TREATMENT OF THE DISCHARGED SOLDIER.

(FROM A SPECIAL CORRESPONDENT.)

THE Government and the people of France are now grappling with a problem which they recognise is only second in its effect on the destinies of the nation to the success of their military operations. After 18 months of war they have to make arrangements for the return to civil life of several tens of thousands of soldiers no longer capable of bearing arms nor, in most cases, of continuing their pre-war occupations. Before peace is declared this number will be augmented and they will then have to cope in addition with the competition of the able men who have also lost their means of livelihood for some cause connected with the war. The same problem in different dimensions will have to be faced in all the allied countries, but the others will have the advantage of being able to note by the success or failure of the different steps taken in France what to imitate and what to avoid.

Development and Organisation of the Movement.

As it has so often happened in her industrial history France was the originator of the idea of educating the infirm in which she afterwards saw herself surpassed by other countries. I am indebted to the excellent report made by Dr. Borne on "La Rééducation et la Réadaptation au Travail des Blessés et des Mutilés de la Guerre" for the information that the famous Paris hospital of Salpétrière was originally an asylum where the disabled were taught to work, founded in 1657 by M. Pomponne de Belièvre, the then Président au Parlement. In the last century several schools for educating the infirm were founded, the most noteworthy being the Marsoulan asylum workshops for both sexes, of which there are four branches in Paris, and the establishment of the Frères de St. Jean de Dieu, which discharges 40 young men each year perfectly able to earn their own living in spite of their infirmity. With such meagre resources it was, of course, impossible to meet the needs of a sudden influx of thousands of disabled soldiers. The danger to the State of a large percentage of unoccupied men was quickly realised, but at first the means taken to remedy matters were more or less chaotic. The presence in the streets of the convalescent soldiers who had lost their limbs aroused the compassion of the public and a great many enterprises were started by private subscription to provide these men with a means of gaining their living. At the present time there are over 50 such organisations in Paris alone, and this only represents a tithe of what is being done, as similar ones are scattered all over France. The absence of any central bureau, where the aims of the different *œuvres* could be tabulated and any overlapping checked, resulted in a certain lack of cohesion and a proportionate waste of energy. The same difficulty was found in the Government where the control of the destinies of disabled soldiers was broken up between the Ministries of War, the Interior, and Labour, with a resulting indescribable confusion. On March 3rd a paragraph appeared in the French press stating that an "Office National des Mutilés et Réformés de la Guerre" would be formed by a combination of these three ministries to deal with every possible provision to be made for the discharged soldier. The Government idea is to gather up all the threads of public and private concerns into its own hands and so achieve more widespread efficiency through centralised effort. The philanthropic idea is that while private endeavour may lack cohesion it undoubtedly possesses more elasticity and variety of form than the state-moulded machine, and is more likely to meet individual requirements than any rigid institution. At the moment both methods are supplementing each other fairly successfully, but the private benevolence that may actually be preferable when dealing individually with restricted numbers is bound to be superseded by the centralised methods which must be adopted by the State when it has to deal with large numbers. The ideal organisation is a central administrative body which will coördinate and control the actions of the executive and provincial bodies to which the actual carrying out of measures designed for securing the proper return of disabled men to civilian life will be entrusted.

Encouragement of the Disabled to do their Best.

One of the difficulties met with at first by both public and private organisation was the lack of enthusiasm, not to say marked disinclination, shown by the majority of the disabled soldiers for learning any trade that will help them to gain a living. I am told by Dr. Bourrillon, the director of the Institut National Professionnel des Invalides de la Guerre de Saint Maurice (Seine), that out of 2000 men he only found 350 who were willing to learn a trade and become self-supporting. The apparently curious attitude is quite easily explained. It must first be remembered that the mental and moral condition of men who have suffered the amputation of one if not two limbs after the strain of a severe campaign is almost always below the normal. When the time came for them to make their choice they were not able to throw off the lassitude of invalidism. This physical and mental inertia left them an easy prey to those discontented spirits who taught the fallacious doctrine that they need not work as they had been wounded in the service of the State, and therefore the State owed them a living; or the equally ill-founded argument that if they gain money by their own efforts they lose their right to a pension. The convalescent homes where the soldiers were often obliged by their wounds to spend long weeks without much occupation were regular forcing-houses for these mischievous ideas, and so were the cabarets where the weekly half-holidays were spent, where the wounded hero was treated to more sophistries as well as more wine than he was capable of withstanding. One of the best antidotes for any misconception of the road where lie his true interests was found to be in a visit to the soldier's home. Once he is back in the familiar surroundings of work the attitude of his women-kind teaches more than any phrases. It is not in the thrifty Gallic temperament to countenance an idler, and it gradually dawns on the hero's astonished mind that if he wants to be the head of his family and not merely a chimney-corner dependent he must be a producer and not an idler. When he was separated from the mischievous counsels of the few discontented spirits who often succeeded in demoralising several hundred men in a hospital, he felt the influence of home atmosphere, and the effect was always noticeable.

This state of things has now greatly changed. The public have had time to think and realise what are the best conditions for which to aim. The help of the doctors and nurses and visitors in the hospitals has been enlisted with splendid results. It was accomplished by means of talking to the disabled and encouraging them about their future, and by the use of cinema pictures showing the *mutilés* at work in their workshops, and post-card illustrations of the different establishments for re-education, as well as by the gentle coercion of the pretty little minor *métiers* of basket weaving, &c., which keep alive the habit of work during the long days of convalescence, besides contributing to the functional re-education. Thus it was impressed on the convalescent that his pension will be quite independent of what he may earn, but will not keep him in idleness, since it is only given to redress whatever disability the pensioner suffers from. He is taught that the duty of a French citizen is not bounded by the defence of the State, but that after he has been wounded in her services his help is still needed in the rebuilding of her commerce. The men are told that the lack of manual labour in France before the war will be accentuated not only by the number of killed but by the lowered birth-rate, and that even the modicum of work the disabled can do makes them a valued asset to the State. Perhaps this point of view was never better expressed than by one of the *mutilés*, who replied to a speech of M. Maurice Barrès at the school in the Quai de la Rapée. "Nous avons fait comme tout Français notre devoir de soldat, mais il nous reste encore un à accomplir, c'est celui de travailler à la grandeur économique de notre chère France."

Choice of Trade.

When the convalescent has made up his mind to work he has to be guided in the choice of a trade. In this choice the three things that influence the doctor's and instructor's advice are: (*a*) that it should be something he takes pleasure in doing; (*b*) that he is capable, physically, of doing it; (*c*) that it should resemble as much as possible the *métier* he followed before the war. The number of trades it is possible for a man who has lost one or more limbs to learn is surprisingly great. At the Belgian school founded at Port Villez, near Vernon, 42 trades are taught, even though the 1200 inmates constitute what is really more a workshop for the production of government supplies for the Belgian army than a school of education for *grands blessés*, of whom there are only 360. The adviser keeps in mind that the primary object is to prevent the man from becoming a public charge, the secondary one being to turn him into an economic asset to the State, so the choice of a new occupation is made with a view to educating his brain to obviate the disadvantage of his infirmity. For example, a man who was formerly a carpenter and whose loss of a leg prevents him from moving quickly is encouraged to study design and the calculation of how much material is needed to build a house, &c., so that he may become a small contractor. Special attention is paid to the fact that after the war there will probably be a great increase in the use of motor agricultural machines to make up for the lack of labour, and a considerable number of *mutilés* are to be taught how to run and repair these machines. Great emphasis is being laid on the necessity for the education to begin as soon as possible. A committee of teachers has been formed to go about the hospitals and encourage pupils to learn bookkeeping, stenography, and typewriting. One notable instance of the success of this scheme occurred at the hospital now run under the auspices of the Scottish Red Cross in the old hotel of Pauline Borghèse in the rue de la Chaise. Here I am informed that a man who had previously been a country labourer was able in two months to pass his examination in bookkeeping, and as soon as he was able to leave the hospital a situation was found for him. Bookkeeping is one of the most favourite employments, and cobbling or bootmaking runs it a close second. The director of one school for the disabled told me that if the men had their way France would be over-run with bookkeepers and cobblers.

Artificial Appliances.

When the trade is chosen and the recovery efficiently complete the functional re-education is begun at once. The men who have lost one arm practise using the other, and as soon as the stump of an amputated limb is in condition the artificial appliance is tried. In the early months of the war there was a deficit in wooden arms and legs, till the Government were obliged to requisition the manufacturers' output and open new workshops, besides ordering considerable quantities in the United States. A number of orthopædic centres were organised in France and her colonies, one for every military region. To these centres amputated men are sent and details of their case noted. When the stump is ready for the artificial limb and the functional education is complete the men are despatched to the centre of professional re-education. Later on a special Commission d'Orthopédie de France was formed to take steps to ensure that the artificial limbs furnished should be of good design, low priced, and of good quality. The limbs will be kept in repair at the Government expense. It is notable that there are far more amputations of legs than of arms, the reason being that the man whose arm is injured is usually able to walk to the nearest dressing-station, while the man wounded in the leg has to wait till help reaches him. The chief Government factories are now at St. Maurice, Montpellier, Lyons, and Bordeaux, and as far as possible the work is done by soldiers who have had their own limbs amputated.

There has been much discussion as to the best type of artificial appliance, and some elaborate inventions have been put on the market. One of the latest and most ingenious has just been evolved by Professor Amar, the Director of the Conservatoire des Arts et Métiers laboratory of military prosthesis. It consists of two models of artificial arms. The first is intended for manual labour and has a steel forearm ending in a kind of crab-like claw. It is very solidly made and can open and shut. The second is meant for lighter and more ornamental purposes. It has a jointed hand and fingers which can be moved without effort by means of an arrangement of steel straps round the chest and shoulders. When the models were shown to the Académie des Sciences a wounded soldier sawed some wood with the No. 1 model, and a violinist who had lost his right arm succeeded in playing his instrument with the model No. 2. While the men are at first keen to possess one of these fancy appliances I am told that in many instances after a few weeks' trial they come back and ask for the humbler but more comfortable peg-leg or hook-arm. In the report on the Lyons School for the Disabled, founded by Senator Herriot, Dr. Carle states that an unexpected visit paid to the

workshops often showed the men working away with what was left of their limbs with surprising agility, the artificial arm being carefully laid aside. The preference for using what they have may be useful later on when the artificial limb gets out of repair, but the doctor does not encourage it. The temporary use of the peg-leg or hook is advised where the stump is not yet in condition to support a permanent artificial appliance. The State owes an artificial limb to every man who has lost a limb in her service, and he can have it at any time he asks for it. A special commission has been formed to provide every soldier not intending to try manual labour with a limb that will disguise his loss as much as possible, and for the labourer a solid wooden arm or leg that he will find practical for his work.

Arrangements for Education of the Men.

Once his *métier* is chosen and his defect remedied as far as possible, the professional education begins. The Government will give to the discharged and disabled soldiers as far as possible all the positions as caretaker, keepers of musées, concierges, special messengers, and employees in Government offices. For these employments little or no training is necessary, but since there are a number of illiterate men among the disabled, classes have been arranged to teach them to read and write. I have seen bearded men wearing the *croix de guerre* trying to master the difficulties of reading with the same dogged courage that won their decoration, and their teachers say they learn with surprising speed. It is a much-disputed question whether the professional school run on institution lines, with special instructors and classes for teaching the different trades and accommodation for housing them, gives better results than the apprenticeship system, where the man receives a lodging allowance and learns his trade in the workshop of an employer. The argument for the former plan is that the men are better looked after and not so exposed to the temptations to which their lowered vitality renders them more than usually liable, while the instruction, being specially adapted to their needs and given by trained teachers, is more likely to have speedy results than that of the foreman in a workshop, who may be an excellent artisan but unable to impart his knowledge. It is generally acknowledged that any attempt to introduce disabled soldiers into the existing houses for the education of infirm civilians would be disastrous owing to the general lack of ambition that is a marked characteristic of the inmates of these institutions.

It is difficult to form an exact idea of the arrangements made for the discharged soldier owing to the lack of uniformity in the great number of charitable undertakings, each run on their own methods. In Paris alone there are nearly 70 organisations run by voluntary contributions, some of them only started since the war and more or less ephemeral, others already existing, with their facilities for housing, education, &c., enlarged to make room for discharged soldiers. In Paris and the provinces there are already some 62 schools for professional re-education and 10 agricultural schools, containing in all about 3755 places for men who wish to be independent and earn their own living. Three of these schools are run by the Government, 8 by the departments, 7 by the city, 4 by Chambers of Commerce, and the rest by private initiative. While they differ widely in details of internal management—cost of up-keep, allowance made to the men, and similar circumstances—they exist primarily for the same object—i.e., to help each soldier by fitting him with the proper appliance, teaching him a trade, finding him a position, and lending him money for a new outfit, to become a contented citizen who feels that he has yet a rôle to play in the forward progress of his country. The magnitude of the task will be realised when it is remembered that, roughly speaking, about a million men are now entitled to pensions, and France may be congratulated on the fact that she has known how to choose wisely the men who are engaged in framing the regulations that will govern the well-being of the return of the discharged soldier to civil life.

THE annual general meeting of the London and Counties Medical Protection Society, Limited, will be held at the offices of the society, 32, Craven-street, Strand, London, W.C., on Wednesday next, May 3rd, at 4 P.M., to receive and adopt the annual report and balance-sheet; to elect president, vice-presidents, officers, and auditors, to fill vacancies on the council, and to transact other business.

WESTERN CANADA.

(FROM OUR OWN CORRESPONDENT.)

Health Report of British Columbia for 1915.

THE health report of British Columbia for 1915 states that the population of the province is estimated to have shrunk from 427,000 to 327,000 owing to the war. The infantile mortality, 79·5 per 1000 births, is very creditable to the province, but 18 per cent. of births registered should have been reported in the preceding year—a delay probably due to the great distances in this spacious province. The chief medical anxieties are typhoid fever and tuberculosis, schemes for dealing with which are foreshadowed. The report is presented by a sanitary inspector, who prepared it under the supervision of Dr. H. E. Young, then provincial secretary. Since his recent retirement there is no medical man in the department. This is said to be for economy, but an epidemic of 350 cases of small-pox is reported, while the death-rate is some 25 per cent. higher than in the previous year.

Economy and Public Health.

Economy is the order of the day in British Columbia, as elsewhere, and, as usual, it was the Health Department's estimate which the Vancouver council desired to prune. But Alderman McIntosh, the chairman, gave some sound advice. The health of the city was, he said, just a matter of dollars and cents. The estimate was for £7000, but if the city could afford £20,000 the death-rate would be reduced and they would have fewer babies dying. As each life was calculated to be worth some £900 to the State, the loss by unnecessary deaths was easily seen. It looked like an economy to cut off the rat-catching bonus, but one case of bubonic plague in Vancouver would very quickly damage the city. This speech impressed the council, and they took 1·6 per cent. only off the estimates, a tribute to the clear thinking and eloquent exposition of the alderman, who doubtless was not without advice from the capable medical health officer of Vancouver, Mr. F. T. Underhill. It is all the pleasanter to find so sound views on hygiene expressed in the largest city of British Columbia, when we remember that the Government of the province thinks so lightly of health that it has done without a provincial health officer for two years. But there is reason to hope that that policy will be shortly reversed. A general election is pending, two Cabinet Ministers have recently been rejected at polls in Vancouver and Victoria by huge majorities, and the Liberal Opposition leaders have promised to local physicians that if elected they will pay particular attention to the hygiene of the province. Of what use is it to the province to spend money on immigration and attracting new settlers if when they come they are attacked by typhoid fever and tuberculosis, as stated in the health report for 1915. Then further immigration of people unacquainted with the province has to be secured to fill their places, a continuing and useless expense to the province, and a damage to the British Empire.

The Tranquille Sanatorium at Kamloops.

The annual report of the King Edward Sanatorium for cases of tuberculosis has just been issued. This is the provincial sanatorium of British Columbia, situated at Tranquille, Kamloops, in the dry belt between the Cascades and the Selkirk Mountains. There were 94 patients generally under care; the cost was reduced this year to 1½ dollars; 16 per cent. were incipient cases, 25 per cent. moderately, and 58 per cent. far advanced. Only 1 per cent. proved non-tuberculous, a credit to the diagnostic acumen of the physicians of the province. But as Dr. C. H. Vrooman, the superintendent, remarks, the sanatorium is provided to care for incipient cases. It is they who get from it the greatest benefit, and until it has not the present number of beds but at least 400 (one for each annual death from tuberculosis in the province) it can do but little materially to reduce the death-rate from this preventable disease.

Prisoners of War in Germany.

The subject of the treatment of prisoners of war in Germany has aroused much interest in Canada. Dr. Bert W. Caldwell, American Red Cross, officially sent to inspect prison camps in Germany in November, 1915, states that at first there were difficulties, and one of the camp commandants was inhumane, but now in Germany the prisoners are well treated. When captured the men are detained till

free of vermin and sent to isolation barracks for a fortnight; they are washed and disinfected every fourth day, and when thoroughly clean are admitted to a prison camp of large sheds arranged on either side of camp streets. Separate nationalities are lodged together, for the English want much fresh air, French prisoners less, and Russians none at all. There have been epidemics of typhus, but there is none now, while more than half the deaths are due to tuberculosis. Insanity is very rare. The food, though good, appears insufficient; stew or soup is given to avoid the use of knives and forks. It is on their kitchen the commandants chiefly pride themselves, and next on their laundries and bath-houses. Individual prisoners are considered. Two orthodox Jews amongst some Russians were becoming emaciated, and it was found that their religion prevented them from eating the food provided, so they were given spirit lamps to prepare their own food. Farms are a part of the camp equipment, and here many prisoners are employed; some work in neighbouring mines or factories. Sanitation is carefully watched and fires prevented. Playgrounds, schools, and means of amusement are always provided.

Victoria, B.C., April 12th.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENTS.)

Women's Medical College at Delhi.

His Excellency the Viceroy on Feb. 17th opened, in the presence of a large and distinguished gathering, the Lady Hardinge Medical College and Hospital for Women in the area of the new city of the Imperial capital. The Hon. Surgeon-General Sir Pardey Lukis, K.C.S.I., K.H.S., V.D., Director-General of the Indian Medical Service, chairman of the Hospital Committee, in an opening speech gave the history of the hospital and enumerated the list of Ruling Princes and others who had so generously supported it. In 1912 Her Excellency the late Lady Hardinge was impressed by the fact that no medical college existed in India exclusively for women, and that consequently the higher medical education of women was conducted by male professors in mixed classes at men's colleges. Accordingly, it was proposed to establish at Delhi a college for 100 students with its attached hospital of 150 beds, in which women would be taught by women to attend on women, and a separate institution as a training school for nurses. Owing to the generous help forthcoming it was possible for Her Excellency to lay the foundation-stone of the new Medical College on March 17th, 1914, a few days before her departure for England, from which country, alas, she never returned. Further subscriptions and endowments are, however, urgently required for this college, which Her Excellency regarded as a pioneer institution ultimately leading to the wide diffusion of medical and sanitary knowledge by training Indian women of the proper class as doctors, health officers, and nurses. The college buildings and hostels are now complete, whilst the out-patient department and one of the hospital blocks are far advanced. No difficulty is anticipated, therefore, as regards the commencement of tutorial work in September next, affiliation to the Punjab University having been sanctioned.

The United Provinces Medical Budget.

Speaking on the Medical Budget at Lucknow, Colonel C. McTaggart, I.M.S., said plague had declined to the minimum. The dispensaries did good work during the cholera epidemic last year, the peculiar feature of which was that it persisted into the winter. Blood examinations had shown that Lucknow was remarkably free from malaria. Colonel McTaggart also alluded to the good work done in tuberculosis by Major C. A. Sprawson, I.M.S., and wished wealthy Indians would endow another hospital in the city and district.

The Bombay Bacteriological Laboratory.

The last report of Major Glen Liston, I.M.S., on the work of the Bombay Bacteriological Laboratory contains exact statistics on the effect of anti-plague inoculation in the Dharwar district. In preparing the statistics, only those houses were taken into account in which inoculated persons were living besides uninoculated and in which plague cases occurred at some date subsequent to the last inoculation; every relevant fact being carefully weighed. It appears that the uninoculated were attacked three times more frequently than the inoculated, and that the latter had nearly ten times fewer deaths. The report testifies to the importance of the work done at the laboratory under Major Glen Liston's direction, not only as to plague and the making of all the anti-plague vaccine used in India, but also as regards preventive medicine and pathological diagnosis for the Bombay Presidency.

The Lady Minto Nursing Association.

The annual report of the Lady Minto Indian Nursing Association for last year shows that the subscribers decreased and the nursing staff was depleted. But despite these difficulties the work of the association appears to have been carried out without interruption, while new responsibilities were undertaken. For instance, considerable assistance was lent to Queen Alexandra's Military Nursing Service. Another excellent piece of work undertaken by the association was the reopening of the Lady Roberts Home at Murree. Special arrangements were made by which Territorial regiments were enabled to participate in the benefits of the association.

Tuberculosis in India.

Dr. Arthur Lankester was entrusted some time ago by the Indian Research Fund with the important task of investigating throughout India, including Burma, the cause and prevalence of tuberculosis in its various forms. In a recent lecture at Rangoon College Dr. Lankester said that in India its annual victims equal the population of Calcutta. In Calcutta itself it causes a rapidly increasing mortality. It is, indeed, the great commercial and educational cities, as well as the big pilgrim centres, particularly of Northern India, which are the foci of the disease in this country. He attributes the fact to a group of causes, some climatic, but far more depending on social customs. The Indian houses, with thick walls and roofs, with little or no space for the ingress or egress of fresh air, are perfect incubating chambers for the phthisis microbe. The disease thrives chiefly, however, because social customs—prominent among them the purdah system—encourage its spread in the family. By far the greatest prevalence of consumption is among middle-class women in the zenanas, irrespective of race or religion. In a crowded Mahomedan ward in Calcutta the deaths from consumption among women last year were six times as numerous as among the ordinary population. In Peshawar the Hindu women, who live in seclusion, suffer quite as much as the Moslem women. The prevalence of the disease under these conditions is due to the fact that girls who, during childhood, have been accustomed to freedom in the open air suddenly find themselves, at a period when their physical resources are subjected to great strain, restricted to the confines often of a single ill-ventilated apartment in which they are compelled to spend the bulk of their existence. The effects of the joint family system superimpose on the purdah system a tendency to overcrowding that places all the members of a middle-class family within reach of infection. Closed-up offices and ill-ventilated schools have the same effect on the male population. Improvement depends on a spread of the knowledge of sound hygienic and sanitary principles, especially among the female population, and this is difficult to attain.

THE SERVICES.

ROYAL NAVY MEDICAL SERVICE.

To be temporary Surgeons:—E. A. Fiddian and R. P. Langford-Jones.

ROYAL ARMY MEDICAL CORPS.

Temporary Captain J. C. Webb to be temporary Major.

T. M. Burn-Murdoch to be temporary Honorary Major whilst employed at the Smithston War Hospital, Greenock.

The following are granted temporary rank whilst commanding Field Ambulances: Majors to be Lieutenant-Colonels: T. E. Fielding, D.S.O., H. St. M. Carter, D.S.O., C. H. Turner, D.S.O., G. E. Ferguson, and F. E. Roberts, D.S.O.

Captain J. W. Lane to be temporary Major whilst commanding a Field Ambulance. Captains to be Majors: H. St. M. Carter, D.S.O., F. E. Roberts, D.S.O., G. E. Ferguson, A. R. Wright, E. C. Phelan, T. D. H. Robinson, A. S. Littlejohns, A. S. Williams, and V. C. Honeybourne.

W. L. Griffiths (late Captain, R.A.M.C., T.F.) to be Captain.

C. C. Coghlan is granted temporary honorary rank of Lieutenant whilst serving with the Australian Volunteer Hospital.

Captain D. J. McLaren, from Somersetshire Light Infantry (T.F.), to be temporary Captain. Temporary Lieutenants to be temporary Captains:—H. W. B. Danaher, H. A. Beaver, H. F. Blood, A. Bloom, J. D. MacEwen, J. V. Buchanan, E. C. Williams, G. R. Lawless, J. C. Lorraine, A. J. Smith, W. A. Kennedy, C. C. Weeks, and D. L. Tate.

M. K. Robertson to be temporary honorary Lieutenant. Temporary Lieutenants who relinquish their commissions:—W. H. Croly, C. S. Palmer, J. T. Anderson, E. T. Pinhey, C. Mathews, J. B. Dawson, B. D. Crichton, J. McG. H. Reid, J. L. Davies, V. C. Pennell, A. E. Gravelle, C. P. M. Joubert, and E. H. Drinkwater.

TERRITORIAL FORCE.

Army Medical Services.

Major (temporary Lieutenant-Colonel) E. J. R. Evatt, Welsh Field Ambulance, to be Assistant Director, Medical Services, Welsh Division.

Captain J. F. Edmiston, from Attached to Units other than Medical Units, to be Deputy Assistant Director, Medical Services, West Lancashire Division.

Royal Army Medical Corps.

Wessex Casualty Clearing Station: Captain A. Greene, from East Anglian Field Ambulance, to be Captain. Lieutenant J. Fenton to be Captain.

London Sanitary Company: Captain H. Beeney relinquishes his commission on account of ill-health.

West Lancashire Field Ambulance: Captain J. E. W. MacFall, from T.F. Reserve, to be Captain. Captain J.E. W. MacFall to be temporary Major. Captain F. W. K. Tough to be temporary Major whilst in command of a Field Ambulance.

London Field Ambulance: To be Captains: Lieutenant (temporary Captain) R. Carswell and W. M. Langdon.

Southern General Hospital: Lieutenant D. R. Dow relinquishes his commission on account of ill-health.

Northern General Hospital: Captains to be Majors: O. H. Chapman, G. A. C. Shipman, and B. McFarland. Lieutenant J. Pearson to be Captain.

East Lancashire Field Ambulance: R. J. Chapman to be Lieutenant.

Highland Field Ambulance: Lieutenant J. B. Foubister to be Captain.

South Midland Mounted Brigade Field Ambulance: O. Cook to be Lieutenant.

South Wales Mounted Brigade Field Ambulance: S. Child to be Lieutenant.

Lowland Field Ambulance: Lieutenant R. Armstrong to be Captain.

East Lancashire Division, Sanitary Section: Lieutenant N. S. Golding, from London Sanitary Company, to be Lieutenant.

Highland Casualty Clearing Station: To be Lieutenants: W. Alexander and A. A. McKenzie.

Attached to Units other than Medical Units.—Major W. F. Roe to be temporary Lieutenant-Colonel whilst in command of a Field Ambulance. Major J. E. B. Wells, from London Field Ambulance, to be Major. Lieutenants to be Captains: M. B. Dawson, D. L. Wall, D. G. Dingwall, and F. F. C. Jagger. W. Taylor to be Lieutenant.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

In the 96 English and Welsh towns with populations exceeding 50,000 persons at the last Census 7947 births and 5766 deaths were registered during the week ended Saturday, April 15th. The annual rate of mortality in these towns, which had been 17·2, 17·7, and 17·7 per 1000 of their aggregate civil population in 1915 (7,312,295 persons), fell to 17·4 per 1000 in the week under notice. The death-rate in the several towns ranged from 6·8 in Southend-on-Sea, 8·5 in Oxford, 8·7 in Ealing, 9·0 in Ilford, and 9·4 in Smethwick, to 22·7 in Middlesbrough, 23·1 in Warrington, 23·9 in Sunderland, 26·7 in West Bromwich, and 29·6 in Tynemouth.

The 5766 deaths from all causes were 102 below the number in the previous week, and included 452 which were referred to the principal epidemic diseases, against 420 and 381 in the two preceding weeks. Of these 452 deaths, 182 resulted from whooping cough, 120 from measles, 65 from diphtheria, 57 from infantile diarrhœal diseases, 16 from scarlet fever, and 12 from enteric fever, but not one from small-pox. The annual death-rate from these diseases was equal to 1·4, or 0·3 per 1000 above that recorded in the previous week. The deaths attributed to whooping-cough, which had increased from 85 to 141 in the five preceding weeks, further rose to 182, and caused the highest annual death-rates of 1·7 in Birmingham and in Darlington, 2·1 in West Ham, and 2·9 in Cambridge. The deaths referred to measles, which had been 115, 122, and 121 in the three preceding weeks, numbered 120; the highest rates from this cause were 1·7 in Salford, 1·9 in Swansea, 3·6 in Grimsby, and 4·0 in Rochdale. The fatal cases of diphtheria, which had been 53, 71, and 45 in the three preceding weeks, rose to 65, and included 13 in London, 8 in Liverpool, 5 in Stoke-on-Trent, 4 each in Leeds and Middlesbrough, and 3 in St. Helens. The deaths of infants (under 2 years) from diarrhœa and enteritis, which had been 65, 66, and 50 in the three preceding weeks, rose to 57, of which 16 were recorded in London, 4 in Manchester, and 3 each in Birmingham and Salford. The deaths attributed to scarlet fever, which had been 12, 20, and 15 in the three preceding weeks, numbered 16, and included 3 in London. The fatal cases of enteric fever, which had been 9, 7, and 8 in the three preceding weeks, rose to 12, and included 2 each in Wigan and Bradford.

The number of scarlet fever patients under treatment in the Metropolitan Asylums Hospitals and the London Fever Hospital, which had been 1783, 1768, and 1778 at the end of the three preceding weeks, fell to 1717 on Saturday, April 15th; 163 new cases were admitted during the week, against 210, 214, and 252 in the three preceding weeks. These hospitals also contained on the aforementioned date 1392 cases of diphtheria, 249 of whooping-cough, 142 of measles, and 40 of enteric fever, but not one of small-pox. The 1433 deaths from all causes in London were 49 below the number in the previous week, and corresponded to an annual death-rate of 17·3 per 1000. The deaths referred to diseases of the respiratory system, which had declined from 405 to 326 in the four preceding weeks, further fell to 323 in the week under notice.

Of the 5766 deaths from all causes in the 96 towns, 190 resulted from violence, 406 were the subject of coroners' inquests, and 1711 occurred in public institutions. The causes of 47, or 0·8 per cent., of the total deaths were not certified either by a registered medical practitioner or by a coroner after inquest. All the causes of death were duly certified in London and in its 14 suburban districts, in Sheffield, Leeds, Bristol, Bradford, and in 61 other smaller towns. Of the 47 uncertified causes, 16 were registered in Birmingham, 8 in Liverpool, 4 in South Shields, 3 in West Bromwich, and 2 each in St. Helens, Manchester, Stockton-on-Tees, and Tynemouth.

HEALTH OF SCOTCH TOWNS.

In the 16 largest Scotch towns with an aggregate population estimated at 2,372,000 persons at the middle of this year, 1090 births and 933 deaths were registered during the week ended Saturday, April 8th. The annual rate of mortality in these towns, which had been 20·7, 19·9, and 19·6 per 1000 in the three preceding weeks, rose to 20·5 per 1000 in the week under notice. Among the several towns the death-rate ranged from 14·1 in Greenock, 14·9 in Clydebank, and 16·1 in Motherwell, to 21·9 in Edinburgh, 22·4 in Kilmarnock, and 23·3 in Ayr.

The 933 deaths from all causes exceeded the number in the previous week by 43, and included 77 which were referred to the principal epidemic diseases, against 82 and 96 in the two preceding weeks. Of these 77 deaths, 36 resulted from measles, 14 from scarlet fever, 10 from whooping-cough, 8 each from diphtheria and infantile diarrhœal diseases, and 1 from enteric fever, but not one from small-pox. The death-rate from these diseases was equal to 1·7, against 1·1 per 1000 in the large English towns. The deaths attributed to measles, which had increased from 23 to 52 in the five preceding weeks, fell to 36, and included 21 in Glasgow, 6 in Kilmarnock, and 2 each in Edinburgh, Paisley, and Coatbridge. The deaths referred to scarlet fever, which had been 12, 8, and 7 in the three preceding weeks, rose to 14, of which 8 were registered in Glasgow. The fatal cases of whooping-cough, which had been 8, 3, and 8 in the three preceding weeks, rose to 10, and comprised 5 in Glasgow, 2 each in Aberdeen and Kirkcaldy, and 1 in Paisley. The deaths attributed to diphtheria, which had been 16, 15, and 8 in the three preceding weeks, were again 8 in the week under notice, and included 2 each in Edinburgh, Aberdeen, and Ayr. The deaths of infants (under 2 years) from diarrhœa and enteritis, which had increased from 8 to 18 in the four preceding weeks, fell to 8, of which 6 were recorded in Glasgow. The fatal case of enteric fever occurred in Falkirk.

The deaths referred to diseases of the respiratory system, which had been 195, 212, and 189 in the three preceding weeks, rose to 193 in the week under notice, and were 11 above the number registered in the corresponding week of last year. The deaths from violence numbered 39, against 29 and 24 in the two preceding weeks.

In the 16 largest Scotch towns 1249 births and 801 deaths were registered during the week ended Saturday, April 15th. The annual rate of mortality in these towns, which had been 19·9, 19·6 and 20·5 per 1000 in the three preceding weeks,

fell to 17·6 per 1000 in the week under notice. Among the several towns the death-rate ranged from 10·0 in Perth, 10·3 in Clydebank, and 12·4 in Motherwell, to 22·2 in Edinburgh, 22·4 in Paisley, and 22·8 in Greenock.

The 801 deaths from all causes were 132 below the number in the previous week, and included 75 which were referred to the principal epidemic diseases, against 96 and 77 in the two preceding weeks. Of these 75 deaths, 42 resulted from measles, 13 from infantile diarrhœal diseases, 8 each from scarlet fever and diphtheria, and 4 from whooping-cough, but not one from enteric fever or from small-pox. The annual death-rate from these diseases was equal to 1·6, or 0·2 per 1000 in excess of that recorded in the large English towns. The deaths attributed to measles, which had been 43, 52, and 36 in the three preceding weeks, rose to 42, and included 27 in Glasgow, 4 in Coatbridge, and 3 each in Edinburgh and Paisley. The deaths of infants (under 2 years) referred to diarrhœa and enteritis, which had been 12, 18, and 8 in the three preceding weeks, rose to 13, of which 6 were registered in Glasgow and 2 in Hamilton. The fatal cases of scarlet fever, which had been 8, 7, and 14 in the three preceding weeks, fell to 8, and included 4 in Glasgow and 2 in Paisley. The deaths attributed to diphtheria, which had been 15, 8, and 8 in the three preceding weeks, again numbered 8 in the week under review; 3 deaths occurred in Dundee and 2 in Edinburgh. The fatal cases of whooping-cough, which had been 3, 8, and 10 in the three preceding weeks, fell to 4, all of which were recorded in Glasgow.

The deaths referred to diseases of the respiratory system, which had been 212, 189, and 193 in the three preceding weeks, fell to 167 in the week under notice, and were 11 below the number registered in the corresponding week of last year. The deaths from violence numbered 23, against 24 and 39 in the two preceding weeks.

HEALTH OF IRISH TOWNS.

In the 19 town districts of Ireland with populations exceeding 10,000 persons at the last Census, 552 births and 469 deaths were registered during the week ended Saturday, April 15th. The annual rate of mortality in these towns, which had been 24·3, 26·0, and 21·5 per 1000 in the three preceding weeks, fell in the week under notice to 21·3 per 1000 of their aggregate population, estimated at 1,148,468 persons at the middle of last year. The death-rate was equal to 23·6 in Dublin (against 17·3 in London and 17·7 in Glasgow), 19·7 in Belfast, 21·8 in Cork, 22·8 in Londonderry, 16·2 in Limerick, and 13·3 in Waterford, while in the 13 smaller towns the mean rate was 21·5 per 1000.

The 469 deaths from all causes were 5 fewer than the number in the previous week, and included 33 which were referred to the principal epidemic diseases, against 47 and 41 in the two preceding weeks. Of these 33 deaths, 16 resulted from measles, 9 from whooping-cough, 5 from infantile diarrhœal diseases, 2 from enteric fever, and 1 from scarlet fever, but not one from small-pox or diphtheria. The annual death-rate from these diseases was equal to 1·5, against 1·4 per 1000 in the large English towns. The deaths attributed to measles, which had been 18, 18, and 13 in the three preceding weeks, rose to 16, and comprised 12 in Belfast, 3 in Dublin, and 1 in Cork. The deaths referred to whooping-cough, which had been 15, 13, and 16 in the three preceding weeks, fell to 9, and comprised 6 in Dublin, 2 in Belfast, and 1 in Lisburn. The fatal cases of diarrhœa and enteritis (among infants under 2 years), which had been 5, 8, and 8 in the three preceding weeks, fell to 5, but showed no excess in any town. The 2 deaths from enteric fever were registered in Dublin and that from scarlet fever in Belfast.

The deaths referred to diseases of the respiratory system, which had been 134, 142, and 120 in the three preceding weeks, numbered 119 in the week under notice, and were 1 above the number registered in the corresponding week of last year. Of the 469 deaths from all causes, 149, or 32 per cent., occurred in public institutions, and 6 resulted from violence. The causes of 11, or 2·3 per cent., of the total deaths were not certified either by a registered medical practitioner or by a coroner after inquest, and included 5 in Dublin; in the large English towns the proportion of uncertified causes did not exceed 0·8 per cent.

CHILDREN AND FRUIT.—At a meeting held on behalf of the National Children's Home and Orphanage at the Mansion House on April 25th, Sir Thomas Barlow said that we did not sufficiently realise the need for making food attractive for growing children. Meat should be well cooked with a good supply of properly cooked vegetables. The importation of bananas and oranges had had a far-reaching effect on the digestion of the children, and if the importation of fruit was interfered with, the children of the humblest classes would certainly suffer.

INFLUENCE OF FEBRILE CONDITIONS ON INOCULATION AGGLUTININS.

To the Editor of THE LANCET.

SIR,—In his adroit and skilful letter in your issue of April 22nd, replying to certain criticisms put forward by Professor Dreyer, Dr. Gibson, and myself, Dr. H. L. Tidy has unfortunately been misled into instituting a comparison between dissimilar materials. Our figures[1] were obtained from cases examined at a much longer average interval of time from their inoculation than Dreyer and Inman's figures for the healthy inoculated individuals[2] whom they examined just a year ago within some few months of their dates of inoculation. It follows that even had the individuals who constituted our material remained in perfect health instead of suffering from febrile disorder, they would still have exhibited a much lower range of agglutinin titre than Dreyer and Inman's subjects, since the agglutinin titre of inoculated persons falls with lapse of time. Hence our figures do not, as Dr. Tidy supposes, support his views, even in their greatly modified form, which he now appears to substitute for his original revolutionary contentions. Moreover, the manner in which Dr. Tidy uses the two sets of figures exposes him to further criticism. For it cannot be accepted as a legitimate statistical procedure to strike *means* as Dr. Tidy does from what are relatively small numbers of observations, where the range of individual variation is so enormous, as, for example, 74 observations in which the range of titre runs from 30 to 1390 agglutinin units, a forty-six-fold variation.

Owing to these misconceptions Dr. Tidy's main argument clearly falls to the ground. It is, therefore, unnecessary for me to trespass on your space by dealing with a number of subsidiary points in Dr. Tidy's letter, in which there are evident other misinterpretations or misunderstandings of what one or other of us has written on the subject of agglutination. I should, however, be glad to take this opportunity of saying, in reference to the "very emphatic" character which Dr. Tidy noted in our denials of his contentions, that while we thought it necessary to express ourselves as forcefully as possible, I trust Dr. Tidy will be willing to acquit our emphasis of any suspicion of intentional discourtesy.

I am, Sir, yours faithfully,

E. W. AINLEY WALKER.

University College, Oxford, April 24th, 1916.

TRANSMISSION AND EXAMINATION OF PLAGUE SPECIMENS.

To the Editor of THE LANCET.

SIR,—In the report of the Manchurian Plague Commission (1911) is a paper by Dr. Broquet recommending his solution—neutral glycerine 20 c.c, distilled water 80 c.c., calcium carbonate 2 gm —as a medium for plague material during transmission to the laboratory, by post or otherwise, in order to prevent putrefaction. It would appear that during the Manchurian outbreak this solution was extensively used with satisfactory results. As in South Africa specimens sometimes take several days to reach the laboratory, and are extremely liable to undergo putrefaction, the solution was welcomed as supplying a much-felt want; it was much used in sending specimens from Queenstown and district to Cape Town during the earlier part of the recent plague outbreak in the Cape Province. These specimens were three or four days, and sometimes longer, in transit. Usually cubes of tissue, measuring about one inch each way, were cut from the lungs, liver, spleen, &c., and forwarded in wide-mouthed bottles. The solution prevented putrefaction, but rendered smears much more difficult to fix on the slides. The best results were obtained by using the central parts of the cubes (least affected by the glycerine) for microscopic and inoculation purposes. It was, however, found that inoculations of such material gave negative

[1] THE LANCET, April 8th, 1916.
[2] THE LANCET, July 31st, 1915.

results in several cases in which there were strong microscopic, clinical or epidemiological reasons for suspecting plague, and it was deemed desirable to carry out bacteriological examinations and inoculation tests at the seat of the epidemic, reserving the Cape Town Laboratory for supplementary or confirmatory investigations. Subsequent experience fully confirmed these suspicions. In one recent case cubes of tissue obtained post mortem from a native child, sent from Queenstown to Cape Town on June 5th, 1915, in Broquet's solution, gave negative results in two guinea-pigs inoculated on the 8th, whereas a guinea-pig inoculated with fresh material on June 5th died of typical plague on the 11th.

It is clear from Dr. Broquet's original paper that stronger solutions have a devitalising effect. He states, however, that 20 to 25 per cent. solution of glycerine prevents the growth of other germs and preserves the virulence of the plague bacillus for eight or nine days, or, with the addition of calcium carbonate, for 13 days, but that the virus is attenuated, as shown by the lengthening of the period between inoculation and death of inoculated guinea-pigs. We are unaware whether his experiments were carried out during a Manchurian winter, but our experience in the warm climate of South Africa has been that transmission in 20 per cent. glycerine solution, even for three or four days, markedly reduces, or even entirely destroys, the virulence of the plague organism for guinea-pigs, and is thus apt to render the examination of material so transmitted useless or even misleading.

Glycerine is extensively employed in the preparation of calf lymph, in order to free the pulp from non-sporulating extraneous organisms. Its germicidal action is, however, greatly influenced by temperature. Dr. F. R. Blaxall[1] remarks: "Glycerine, in fact, has no germicidal action of itself, but in conjunction with heat it is a powerful germicide, and this action varies directly with the temperature." Glycerinated lymph pulp stored at or below freezing point shows practically no reduction in its original bacterial contents, but if kept at room or higher temperatures for a few days the reduction is marked, the lymph frequently becoming sterile in two or three days. We have found by direct experiment with cultures that glycerine rapidly affects the virulence of B. pestis when kept in contact with the organism for 12 hours at 37° C. or even at much lower temperatures. Further investigations are being carried out, but it seems highly probable that glycerine solutions of any strength are not suitable fluids in which to forward specimens of plague material for diagnosis by animal inoculation when the outside temperature is above freezing point.

The method of shaving the abdomen of a guinea-pig and rubbing in infected material, as advocated by Albrecht and Ghon, has not in our hands given satisfactory results when the virulence of the plague organism has been lowered by putrefaction or by preservation in alkaline glycerine solution. With putrefactive material the most reliable results have been obtained by preparing an emulsion in sterile beef broth or normal saline solution and inoculating several guinea-pigs subcutaneously with varying quantities of this emulsion. Four animals are generally employed, three being given 0·5 c.c., 0·25 c.c., and 2 drops respectively, and the fourth merely a prick with the needle of the inoculating syringe. Animals receiving the larger doses frequently die early from general septicæmia and without showing definite post-mortem or microscopic evidence of plague. Those receiving the smaller amounts often survive for five or six days, sometimes even for seven or eight days, and then die of plague. As a rule, the longer the period between inoculation and death the more characteristic are the naked-eye appearances in the spleen, liver, and suprarenal bodies. Guinea-pigs and other experimental animals have a certain "resistance" to plague, and when inoculated with mild strains, or with organisms the virulence of which has been attenuated by unfavourable influences of any kind, do not always develop the disease. Hence the importance of inoculating *several* animals and varying the dose. Even then a negative result cannot always be safely regarded as conclusive.

We are, Sir, yours faithfully,

J. A. MITCHELL, M.B., Ch.B. Glasg, D.P.H. Camb.,
Assistant Medical Officer of Health for the Union of South Africa.

G. W. ROBERTSON, M.R.C.S. Eng., L.R.C.P. Lond.,
Government Bacteriologist for the Cape Province.

Cape Town, March 4th, 1916.

[1] Report of Medical Officer to Local Government Board, 1902-1903.

FUNCTIONAL NERVOUS DISEASE.

To the Editor of THE LANCET.

SIR,—Dr. Elliot Smith's accusation that I have "used" a protest against Dr. Forsyth's statement "to attack the whole theory of the rational treatment of incipient mental disturbance" is, if Dr. Elliot Smith will pardon me for saying so, unworthy of him, both in manner and in substance—in manner because in the question-begging phrase "of course" he airily assumes that he must be right and I must be wrong, and in substance because I did not attack a whole theory or any part of a theory. I attacked a practice. I attacked it because I consider it pernicious and immoral, degrading to those who use it and brutalising to those on whom it is used; and I adduced convincing evidence that what I say is true. If Dr. Elliot Smith wishes to show that I am wrong he must either shake my evidence or show that my conclusion does not follow from it. He does neither. He says "of course" I am wrong. It is equally open to me to say that of course he is wrong, but I do not stoop to this method of controversy. But supposing I did attack the "theory" on which the practice of psycho-analysis is founded, does Dr. Elliot Smith assert, as his words imply, that this theory is the sole theory on which the rational treatment of incipient mental disturbance can be founded? If so, he is demonstrably and grossly wrong, and he has only to refer to THE LANCET of March 4th and 11th to see that he is wrong. This is, or was, a free country, and if Dr. Elliot Smith chooses to call the method of treatment that he describes a theory, and a whole theory, I shall not object, whatever I may think; but if he considers that it is psycho-analysis, or that it is novel, he is mistaken. Dr. Elliot Smith may call it what he likes, but it has always hitherto been called "obtaining the confidence of the patient," and every physician worth his salt has been practising it from the time of Æsculapius, and no doubt much longer.

As this controversy has been reopened, I may as well answer the letter in which Dr. Ernest Jones[1] attempts to "dissipate confusion" as to the meaning of psycho-analysis. This is how he attempts to dissipate confusion. He says that psycho-analysis denotes "(*a*) a certain technical method for the exploration of the unconscious mind?" I do not find in this any tendency to dissipate confusion. Quite the contrary. It would not dissipate confusion to refer a physicist to a certain technical (I thank thee, Dr. Ernest Jones, for teaching me that word) method for the exploration of the liquid solid, the refrigerating fire, or the bursting vacuum; and these things are precisely on a par with the unconscious mind. Next, psycho-analysis denotes "(*b*) the theory *necessarily* involved in the use of this method (one presupposing, among other things, psychical determinism, the law of causality, &c.)." If the theory, or the method, presupposes psychical determinism, and if by psychical determinism Dr. Ernest Jones means the negation of free will, then the theory, or the method, presupposes what is contradicted by the whole experience of the whole human race; and such a presupposition is an insecure foundation on which to build a theory or a method. Nor will it tend to dissipate confusion to presuppose the law of causality, until we know what is meant by the law of causality. If it means the law of causation then this expression has many different meanings, and confusion will not be dissipated until Dr. Jones tells us in which meaning he uses the term. Lastly, psycho-analysis "denotes the accompanying study of the subject-matter concerned." Concerned in what? In the technical method? Then, presumably, the subject-matter is the unconscious mind. It is the footless stocking without a leg. It is the knife that has neither blade nor handle. It is nothing. Concerned in the theory that presupposes a falsity and an ambiguity? Then I am afraid confusion will not be dissipated. Whether the patients I have seen who have suffered disastrously from psycho-analysis have, as Dr. Ernest Jones asserts, been treated by those who have not been competently trained, I do not know; but this I know, that they have been treated by men who have written freely on psycho-analysis, and therefore if they have not been competently trained they are doubly impostors.

Since Dr. Ernest Jones's letter appeared in THE LANCET, he has been lecturing on psycho-analysis to the Child Study Society, and has been telling the teachers of children that "there was too much repression of tendencies."

[1] THE LANCET, March 11th, p. 588.

This, in the mouth of a psycho-analyst, will be understood to mean sexual tendencies, and as the warning occurs immediately after Dr. Jones has been treating of "the question of sexuality in children," it is natural to suppose that he did mean sexual tendencies. If Dr. Jones did not mean that children are to be encouraged to masturbate, he has expressed himself very unfortunately, for his words, as reported, will bear this interpretation, and there is nothing in the "theory" of psycho-analysis to discountenance it.

I am, Sir, yours faithfully,

April 22nd, 1916. CHAS. A. MERCIER.

THE TRANSLATION OF JUNG'S ANALYTICAL PSYCHOLOGY.

To the Editor of THE LANCET.

SIR,—The Collected Papers on Analytical Psychology by Dr. C. G. Jung I find to be announced in a publisher's list as translated by Dr. Constance E. Long. Of nine papers (263 pages) especially translated from the German for this book six (224 pages) were done entirely by my wife and myself; a further two (26 pages) were completely revised and partly re-translated by myself.

I am, Sir, yours faithfully,

London, W., April 24th, 1916. M. D. EDER.

THREE CASES OF ANGINA PECTORIS TREATED BY A NEW METHOD.

To the Editor of THE LANCET.

SIR,—The treatment adopted in the following three cases of angina pectoris may throw additional light on this baffling affection.

Dr. X, an old friend of mine, had his first attack last summer while on holiday. Before this he was strong and healthy, a rapid and untiring walker, and his heart was sound. Owing to the war he had suffered many anxieties. His appetite failed and he lost steadily both energy and weight. About a week after his holiday the second attack occurred, and from that time the attacks were more frequent and of awful severity, often two or three on a day; the usual remedies, nitrite of amyl, &c., lost their effects. He then told me of his condition, calling me in to sign his last papers and save an inquest. Being laid up myself just then, I handed my friend over to a colleague, from whom he derived the greatest comfort and relief. By my advice he took absolute rest in bed for three or four weeks, and there was no return of the attacks, but he had severe after or minor pains in chest and left arm; also on the slightest exertion these pains attained ominous forebodings of a severe spasm.

During my own illness I reflected on my friend's sad state, and it struck me that, whatever the original cause, if the minor pains could be got rid of the major would not follow, and that hope of ultimate recovery would be considerable. I formed the opinion that the minor pains were due to *partial* constriction of the small vessels, and that the major were due to *entire* constriction. I then considered, mentally, a small vessel thus constricted, and that forces acting either in the line of the vessels or transversely would mechanically release the constriction, and that similar results would in general follow where there was a condition of tortuosity. Early in December of last year I again called on Dr. X after some weeks, and found him in much pain in both arms and chest. At once I got him to grasp the top bar of the bed with both hands, letting most of his weight fall on the now strongly stretched arms for some 40 seconds. After a short rest he repeated the process some five or six times. Result: Immediate cessation of all pain in arms and some relief of the chest. I now got him on the floor to grasp the bar at the end of the bed with both hands behind his back, bending forward at an angle of about 60°, the chest thrown forward, and the head back, thus subjecting the muscles of the affected area to strong tension. This he repeated some half-dozen times, each lasting about 40 or 50 seconds. Result: Immediate cessation of all pains in the chest, the sense of constriction completely vanishing. He now went to his bath, and for the first time the exertion of washing caused only the merest suspicion of the old ominous forebodings of ill. For some weeks the process was continued about every two hours, the minor pains occurring with less severity and frequency; and it is important to note *that on no occasion did the stretching fail to give immediate relief*, though the operation must have been performed hundreds of times. No medicine was taken. Dr. X is now at work and able to walk with almost his old rapidity.

The next patient, aged 35, was employed in lifting heavy parcels. His attacks were severe and only ceased on inhaling nitrite of amyl. When he came to me a few weeks ago he was suffering from rather severe minor pains. He always knew when the major attack might be expected from the increasing severity of the former. I gave him no medicine and explained to him the operation mentioned. Result: Immediate cessation of pains on every occasion but one, *and absolute stoppage on three or four occasions of the major spasm* that he knew would otherwise develop.

The third case was that of a French polisher, aged 52. In his case relief was not so rapid, though after a minute or two he described his sensation of comfort as accompanied by a "tingling and rushing of blood over his face and neck." He has also been under this treatment for some three weeks only and is able to rest in bed, which the previous patient, unfortunately, was unable to do.

As to the cause, or even predisposing cause, of this affection I am of opinion that we know very little. If I were to draw a conclusion from these three cases, I should be inclined to say that, as a predisposing cause, long-continued anxiety or worry plays a large part. As to the cause of the pain, I believe that *partial* constriction of the vessels gives rise to the minor, and that complete constriction causes the severe, or major, attacks, and that the greater the area involved and the more absolute the constriction of the vessels the more severe is the attack. Also, that the conditions of atheroma and arterio-sclerosis, with consequent loss of arterial elasticity, are a very large factor of the pain, and that they are in no way a part of either the original or predisposing cause. We rarely hear of anyone of 60 suffering from angina pectoris, and after 65 the affection is practically unknown; so that the more pronounced the atheroma, the more immune we become. I also conclude that there is no distinction, beyond the degree of pain, between true angina and false. The child simply suffers less because better equipped with elastic tissue.

If any sufferer of my own profession should care to write to me for further information, I need hardly say it will give me great pleasure to answer any questions that may contribute to his comfort.

I am, Sir, yours faithfully,

SAMUEL CONSTABLE.

25, Belmont-road, West Green, N., April 22nd, 1916.

SHAKESPEARE AND MEDICINE.

To the Editor of THE LANCET.

SIR,—You may perhaps be able to find room for the following brief notes relating to Shakespeare and medicine.

1. *A medical pall-bearer.*—The *Evening Standard* of March 15th, 1913, recorded the following inscription found upon a dilapidated tombstone in the old Masonic graveyard of Fredricksburg, Virginia:—

> Here lies the body of
> EDWARD HELDON,
> Practitioner in Physics and Chirurgery. Born in Bedfordshire, England, in the year of our Lord 1542. Was contemporary with and one of the pall bearers of William Shakespeare of the Avon. After a brief illness his spirit ascended in the year of our Lord 1618, aged 76.

The inscription is in old English letters, dim but traceable. It must be added, however, that the *Evening Standard* of three days later contained a letter signed "Edward S. Dodgson, M.A. Oxon.," throwing considerable doubt upon the authenticity of the above inscription.

2. *Dr. Hall's patients.—Notes and Queries*, August 28th, 1915, contains a list of patients attended by Dr. John Hall, Shakespeare's son-in-law and physician. This list, compiled by Hall himself, mentions "Mrs. Hall, my wife," and "Elizabeth my onely daughter," but does not mention Shakespeare.

3. *A medical writer on Shakespeare.*—A little known but excellent work is "Shakespeare and his Times," by Nathan Drake, M.D. (1766–1836), two volumes, 4to, 1817. This work was favourably reviewed by the *Gentleman's Magazine* at the time of its publication. Dr. Drake also wrote (1828) "Memorials of Shakespeare," a sort of anthology of all that had been written to date upon the poet and his works both at home and abroad. Both of Dr. Drake's works are in the British Museum.

4. *The cause of Shakespeare's death.*—There seems to be little doubt that the poet's death was occasioned by inebriety. A month before he died Shakespeare indulged in a symposium with his boon companions Michael Drayton and Ben Jonson, caught a chill on his way home, and did not leave his bed again. These facts are recorded in the MS. diary of the Rev. John Ward, vicar at the time of Stratford-upon-Avon. The vicar's diary is in the possession of the

Medical Society of London and in the keeping of the society's learned and courteous librarian, Mr. George Bethell.

I am, Sir, yours faithfully,

S. D. CLIPPINGDALE, M.D. Aberd.

Holland Park-avenue, W., April 23rd, 1916.

THE WITTENBERG CAMP.

To the Editor of THE LANCET.

SIR,—Psychology in relation to the war has been prominent in your columns of late. In connexion therewith the letter of Sir William Milligan is of considerable interest. The natural indignation and horror at the Wittenberg atrocities will, of course, be shared by every decent human being in the world. It is perfectly certain that *if the facts were allowed to be known by them* a large proportion of German doctors would repudiate the action of Aschenbach with shame and loathing. Does Sir William Milligan really think that all our confrères in Germany, who have been welcomed and honoured in this country, have suddenly become "beasts"? The idea is unthinkable and absurd. To pass such a wholesale condemnation upon them as Sir William Milligan suggests would be hasty, undignified, and on a moral and intellectual level with the banishment of German music from our shores. When the passions of the present time have disappeared no one will regret more than Sir William Milligan himself the ill-considered proposal he is now making.—I am, Sir, yours faithfully,

Finchley, April 23rd, 1916. J. S. BOOTHROYD, M.D.

Obituary.

JAMES HARPER, M.D. LOND., M.R.C.S.,

COLONEL AND ASSISTANT DIRECTOR OF MEDICAL SERVICES, 1ST LONDON DIVISION (T.F.).

WE have already recorded the death of Dr. James Harper, which occurred on March 24th. He was born at Leith in 1857, but his father, a medical practitioner, very shortly afterwards moved to Windsor, where Dr. Harper's boyhood was spent. He was educated at Amersham Hall School, Reading, and having matriculated at the University of London he entered as a student at St. Bartholomew's Hospital. His career at "Bart.'s" was very successful. He passed his medical examinations with ease, took honours in obstetric medicine at the Final M.B. Examination, and in 1883 graduated as M.D. Lond. He filled the office of house surgeon at St. Bartholomew's Hospital and afterwards was successively house physician to the Royal Hospital for Diseases of the Chest, and resident medical officer and anæsthetist to the Hospital for Women, Chelsea. Having thus fitted himself for practice he took a house in South Kensington and quickly gathered about him a large practice.

But Dr. Harper's activities were not limited by the demands of his practice, and for many years he devoted a good deal of time to the Medical Corps of the Volunteers. Joining the Volunteer Medical Service Corps in 1894 he in due course became captain, major, and then lieutenant-colonel in that force. In April, 1908, he was appointed to the 3rd London Field Ambulance, and in 1912 was promoted to the rank of colonel and made A.D.M.S., 1st London Division. He was intensely interested in his military duties and threw himself into the work of training his ambulance units with great enthusiasm and success. At the outbreak of the war he laid aside his practice and devoted himself wholly to his work as A.D.M.S., and he only gave up this work when he was a broken man, too ill to do it.

One who knew him well writes:—"His great ability and industry were associated with such a robustness of character and also such a merry humour that all who knew him were drawn to him and were helped by his example. In his private practice his patients highly valued him, for his medical knowledge and experience were combined with such kindliness of heart and strong commonsense that they found him to be not only a wise medical adviser but a strong and true friend. The high esteem in which he was held was strikingly shown by the large gathering of mourners who attended his funeral service. Harper was a man of fine presence; and in his physical vigour as well as in his strength of character, tempered by a deeply religious spirit, he showed the influence of his Scottish parentage. About four years ago he underwent a serious operation, and although he recovered and resumed his practice his work afterwards was often carried out under difficulty. Early this year signs of increasing illness showed themselves, and in spite of rest and the efforts of trusted and attached medical friends, his weakness increased and he passed away on March 24th. None who ever knew James Harper will forget him, for his high standards and strength of character made him a marked man."

Dr. Harper was twice married, first to Helen Watson Brand, daughter of the late Alexander Brand, United States Consul, Aberdeen, and later to Annette Ellen Grant, youngest daughter of the late Admiral Henry Duncan Grant, C.B. He left three sons and two daughters, and one son was lost in the explosion on the *Princess Irene*.

CORNELIUS HANBURY, M.R.C.S., L.S.A., F.C.S., F.I.C.,

CHAIRMAN OF THE BOARD OF DIRECTORS OF ALLEN AND HANBURYS, LIMITED.

Mr. Cornelius Hanbury, of the Manor House, Little Berkhampstead, died on April 11th, aged 88, having been born on Nov. 29th, 1827. He was the only son of Cornelius Hanbury, of Plough-court (who died in 1869), and his second wife, Elizabeth, daughter of John Sanderson of Avonthorpe and cousin of the present Lord Sanderson. Mrs. Cornelius Hanbury was well known for her Christian and philanthropic work in connexion with the cause of anti-slavery and the prison reforms of Elizabeth Fry, dying in 1901 at the remarkable age of 108. Both Mr. and Mrs. Cornelius Hanbury were members of the Society of Friends and ministers in the society. Mr. Cornelius Hanbury, the son, after education under a private tutor became a student at St. Bartholomew's Hospital. From 1845 to 1850 he was apprenticed to Dr. (afterwards Bishop) Henry Callaway, and lived with him in Bishopsgate-street for about a year. In 1849 he became M.R.C.S., and in 1850 L.S.A. In 1876 he was elected treasurer of the Pharmaceutical Society, but resigned this office in 1878. He was a member of the council of the society from 1875 to 1878. In 1871 he was nominated a governor of St. Bartholomew's Hospital and for some years held the office of almoner. Towards the end of 1849 Mr. Cornelius Hanbury first began to attend daily at the pharmacy at Plough-court, then under the control of his uncle, Daniel Bell Hanbury, and his father, Cornelius Hanbury, senior. There he became intimately associated with his cousin, Daniel Hanbury, F.R.S., who made some important scientific contributions to materia medica.

In 1868, with the retirement of Daniel Bell Hanbury and Cornelius Hanbury, senior, the two cousins became the acting partners of the firm. On the retirement of Daniel Hanbury in 1870, Cornelius Hanbury became proprietor of the business. A comparatively young man, he had the sole control of a well-appointed and established business, which, starting in the hands of Sylvanus Bevan in 1715, had grown up with the sound traditions laid down by its founder. A generation of Hanbury control had preserved the same traditions. Mr. Cornelius Hanbury, while maintaining the same ideals, looked far ahead and realised the possibilities of specially developing the wholesale and manufacturing lines of the firm. Years of foresighted expenditure and gradual expansion have followed, resulting in the many undertakings and branch establishments of this firm not only in this country but in various parts of the world. Cornelius Hanbury combined strength of purpose with the utmost simplicity. His life and example were an inspiration to all those with whom he came in contact, and the news of his death will be felt, not only by those at home, but by a great number of the firm's employees now serving at the front. The general affection and respect of the firm's employees towards the chairman were shown in 1896, when the staff presented Mr. Cornelius Hanbury with a portrait of himself painted by Mr. Percy Bigland. He married in 1850 Sarah Jane, daughter of Frederick Janson, of Lloyds and Stoke Newington. She died in 1903. His elder and only surviving son, Frederick Janson Hanbury, F.L.S., now to become chairman of the board of directors, was born at Stoke Newington on May 27th, 1851. Though born and brought up as members of the Society of Friends, both Mr. Cornelius Hanbury and his wife and children joined the Church of England. The interment took place at Highgate cemetery on April 14th, the funeral service having been held at St. Andrew's, Little Berkhampstead.

The War.

THE CASUALTY LIST.

THE following names of medical officers appear among the casualties announced since our last issue :—

Wounded.

Lieutenant G. L. Kennedy, R.A.M.C., attached to the Royal Warwick Regiment.
Captain H. G. Peake, R.A.M.C.

DEATHS AMONG THE SONS OF MEDICAL MEN.

The following sons of medical men must be added to our lists of those who have fallen during the war :—

Lieutenant A. Mathews, Cheshire Regiment, only son of Mr. F. E. Mathews, L.R.C.P., M.R.C.S., of Nantwich, Cheshire.
Lieutenant F. R. Heuston, Canadian Infantry, last surviving son of the late Dr. F. T. Heuston, of St. Stephen's-green, Dublin.

THE REBELLION IN DUBLIN.

The unpreparedness of the Government has subjected the capital of Ireland to unmeasured inconvenience as well as to grave humiliation. The roll of killed and wounded following on the armed revolt is already known to be slight, and the actual figures will possibly be in the possession of our readers before this issue of THE LANCET appears. But from the medical point of view the figures, when they are forthcoming, will not represent the damage done; the evil of such catastrophes is far-spreading and difficult to control. Mentally and morally, all the weaker and less stable inhabitants of a district which has suffered under an armed *émeute* are definitely damaged. This fact rapidly makes itself known to all medical practitioners and is reflected in all hospital statistics. At the same time the machinery for securing the public health is dislocated. It is therefore of the utmost importance that order should be re-established in Dublin and law again made effective with the least possible delay. Dublin is not a city where the conditions of public health can stand much deterioration.

BENEVOLENT FUNDS FOR THE SERVICES AUXILIARY TO THE ROYAL ARMY MEDICAL CORPS.

It has been suggested that benevolent societies be formed for the benefit of the families of officers and other ranks of the Medical Services auxiliary to the Regular Royal Army Medical Corps—viz., the Special Reserve, the Territorial Force, and New Army. Funds would be raised by voluntary subscriptions, and it has been proposed that each branch of the Service should appoint a committee of 5 to 7 members to administer its own funds.

A meeting, to be presided over by the Director-General, will be held in the lecture theatre of the Royal Army Medical College, Grosvenor-road, S.W., on Wednesday, May 10th, at 3 P.M., and it is hoped that as many officers as possible will attend. In the meantime any inquiries may be referred to Lieutenant-Colonel G. St. C. Thom, R.A.M.C., War Office, S.W.

THE CONDITIONS OF EXCHANGE OF INVALID PRISONERS.

We learn through a German source[1] of the publication by the Prisoners' International Agency of a paper entitled "Nouvelles de l'Agence Internationale des Prisonniers de Guerre." It is to appear weekly at a cost of 5 francs per annum. The first number contains the conditions regulating the return to their own country or the sending to Switzerland of invalid prisoners of war. The conditions which entitle a private to be sent back home are as follow: (1) Complete or partial loss of one or more limbs (at the least, a foot or an arm); (2) loss of use of a limb through ankylosis, permanent palsy, atrophy or contraction of muscles, pseudarthrosis, spinal injury which affects movement materially; (3) confirmed palsy, important from its site or extent; (4) brain injury with severe consequences (hemiplegia or impairment of cerebral function); (5) spinal injury with severe consequences (paraplegia, various palsies); (6) blindness of both eyes; (7) considerable mutilation of the face, severe injuries of the mouth; (8) permanent cachexia from wounds; (9) advanced pulmonary tuberculosis; (10) cachexia due to internal disease; and (11) incurable mental disease. For officers and non-commissioned officers the conditions are slightly different: (1) applies to complete or partial loss of *several* limbs; (4), (5), (6), (8), (9), (10), and (11) apply exactly; (2), (3), and (7) do not apply at all. The Red Cross requests that this list should be used when applications are made in order to avoid disappointment. To entitle to treatment in Switzerland the conditions are as follows: (1) very extensive skin diseases, commencing malignant tumours, extensive glandular swellings, chronic glandular suppuration; (2) chronic blood diseases (leukæmia, pernicious anæmia); (3) extensive mutilation of the face, severe injuries to the mouth insufficient to entitle to an exchange; (4) blindness of one eye, with diminution of the sight of the other by one-half or less (glasses necessary); (5) double deafness; (6) moderately advanced pulmonary tuberculosis; (7) severe nervous diseases, especially severe hysteria; (8) severe heart disease; (9) severe chronic gastric disease demanding prolonged special dietetic treatment; (10) loss of a limb, at the least of a hand or a foot (for officers and N.C.O.'s); (11) shortening or marked stiffness resulting in considerable impairment of the limbs, pseudarthrosis, muscular atrophies; and (12) chronic diabetes or nephritis with constant presence in the urine of a considerable quantity of sugar or albumin. Germany asked to have severe rheumatism recognised, France agreed while asking for more exact definition. We have already noted that a sanitary commission of 10 Swiss doctors was appointed to see that these conditions are adhered to. Every prisoner has the right of demanding an examination by the commission without risk of punishment if his claim should be rejected. In later numbers of the *Nouvelles* the list of exemptions for Switzerland is further increased by the addition of commencing asthma, chronic poisoning, well-marked articular gout, general debility, all consequences of a disease or injury giving rise to unfitness for service of at least a year's duration. It will be seen that the mesh is much wider for treatment in Switzerland than for return home. In another paper (*Deutsch. Med. Wochenschr.*, 1916, No. 12) it is stated that certain conditions are to exclude from Switzerland—viz., all severe nervous and mental diseases requiring institutional treatment, chronic alcoholism, contagious diseases of any kind at their infectious stage (infectious gonorrhœa, primary and secondary syphilis, trachoma, &c.). These conditions affect at the moment only French and German prisoners. No reciprocal engagements for sending invalid officers to Switzerland have yet been arrived at between Germany and Great Britain.

[1] War Supplement to the Münchener Medicinische Wochenschrift, 1916, No. 12.

THE SALE OF NARCOTIC DRUGS TO SOLDIERS.

In commenting upon the ease with which such potent drugs as morphine and cocaine could be purchased by soldiers, even without any infringement of the existing law affecting the sale of poisons, it was intimated in THE LANCET of Feb. 26th that the military authorities might find it desirable to take steps to prohibit the sale of such drugs to men on active service. Action has now been taken in this direction, a regulation having been made under the Defence of the Realm Act which provides that the Admiralty or Army Council may by order prohibit, either absolutely or except on compliance with such conditions as may be specified in the order, the sale or supply to or for any member of any of His Majesty's Forces of any narcotic or stimulant drug or preparation specified in the order, and if any person acts in contravention of any such order he shall be guilty of a summary offence against these regulations. Should the naval and military authorities deem it expedient to use their powers in pursuance of this regulation the position of pharmacists would be made clearer. While, no doubt, in the majority of cases pharmacists would refuse to sell narcotic drugs to soldiers in uniform—except, of course, to officers of the Royal Army Medical Corps—unless they were satisfied that the circumstances of a particular case justified the transaction, it can

be well understood that it is not always an easy procedure to refuse to grant a customer's legal request. If an order were made absolutely forbidding such transactions, a soldier would not put the pharmacist in the position of having to decline to sell such drugs, and the pharmacist himself would be satisfied in the knowledge that a disappointed client could not get what he wanted at another chemist's shop in the same area.

THE PROPOSAL FOR A COLLEGE OF NURSING.

We have referred already to the proposal received from the matron-in-chief of the Joint War Committee of the British Red Cross Society and the Order of St. John of Jerusalem, in a letter signed by the Hon. Arthur Stanley, chairman of the Committee, suggesting the foundation of a College of Nursing. We have now received a copy of a letter which Mr. Stanley is sending to the authorities of more than 200 of the nursing schools of the United Kingdom. The idea is that the College shall take its place eventually as the central organisation of the nursing profession of the United Kingdom. In the first week in April a conference was held at St. Thomas's Hospital, when over 200 representatives were present from England, Wales, Scotland, and Ireland. Mr. Stanley explained the circumstances which led to the establishment of the College of Nursing, and laid stress upon the desire of the council to form as speedily as possible such a Consultative Board as would be representative of all parts of the United Kingdom and of all branches of nursing. Nursing authorities are requested within the next month to nominate not more than two representatives upon the Consultative Board of the College, the duties of which will be to advise the council in many matters of policy and procedure. The council numbered at first 15 persons, but has been increased by coöptation to 23, consisting largely of the matrons of some of the chief hospitals and lady-superintendents of some infirmaries, together with six members of the medical profession, Sir Cooper Perry being the honorary secretary. This number may be increased to 30 members. The College has been registered as "Limited," as to do otherwise would have occasioned delay and difficulties, and the Memorandum and Articles of Association have been drawn to give the widest possible powers. It is proposed that the College, which in its early years will be largely guided by the experience of the heads of the various training schools, who form a majority of the first council, shall, when it attains maturity, become broad-based and democratic in constitution and self-governing. Some objects aimed at are uniformity of curriculum, the one-portal system of examination, only one certificate of general training for all nurses wherever trained, inducing backward institutions to improve their curricula and improved accommodation for study, and the establishment of local boards with power to act in their respective areas with the powers, authorities, and discretions vested in the council, and eventually, when substantial unanimity has been reached, to present a Bill to Parliament to gain legal status.

WOUNDED ALLIES RELIEF COMMITTEE.—To the work of this Committee there has been added recently the maintenance of a large hospital at Lyons. This hospital, which was formerly the Lycée de Saint Rambert, and has been used for hospital purposes by the French, holds 300 beds, and will take the place of the Committee's Military Hospital at Dieppe, which is now inadequate to the demands made upon it. Dr. V. H. Rutherford, who was one of the passengers on the ill-fated *Sussex*, is now at Lyons on behalf of the Committee, superintending the arrangements for the transference of the smaller hospital to the larger one. The staff of the hospital, like that of the Military Hospital maintained by the Committee at Limoges, is English.

BRIGHTON MILITARY HOSPITALS.—On the evacuation by the Indians of the three great hospitals used by them at Brighton—the Royal Pavilion Buildings, the Kitchener Hospital (formerly the workhouse), and York-place school—the buildings were reorganised to receive British wounded. On April 15th the first batch arrived. There were 90 cot cases and 81 sitting, and they were taken to the Kitchener Hospital. The Royal Pavilion Hospital is to be used exclusively by soldiers who have lost a limb.

OBITUARY OF THE WAR.

WALTER LINNEY HAWKSLEY, M.B., CH.B. LIVERP., D.P.H.,

MAJOR, ROYAL ARMY MEDICAL CORPS (T.).

Major Walter Linney Hawksley, who died on active service in France, was the eldest son of the late Dr. H. L. Hawksley, of Southport. He was educated at University School, Southport, proceeding afterwards to Liverpool University, qualifying in 1904. He had a long connexion with the Second West Lancashire Field Ambulance, and was with this unit at their annual encampment when war broke out, and at once proceeded to active service, being promoted major in April, 1915. Dr. E. W. Hope, medical officer of health of Liverpool, writes: "The tragic death of Major Hawksley, whilst on active service in France, removes from the service of the Liverpool corporation a brilliant assistant medical officer. Dr. Hawksley had always been associated with Liverpool, and was a graduate of the Liverpool University. A university career of distinction was followed by a period of usefulness spent in work at the Liverpool South Dispensary and the David Lewis Northern Hospital. His first association with the corporation was as a resident medical officer at the Fazakerley Hospital. Administrative ability and enthusiasm for his work received deserving recognition when he was given control of the tuberculosis wards. Subsequently he held the post of assistant school medical officer, and ultimately was appointed an assistant medical officer of health to deal with problems relating to tuberculosis. Following the passing of the National Insurance Act, Dr. Hawksley naturally attained the additional position of acting chief tuberculosis officer, a post for which his previous experience gave him exceptional qualification. The harmonious relationship which now exists between the Insurance Committee and the corporation serves as a lasting monument to his unfailing tact and administrative ability, for upon his shoulders fell much of the original work of organising the Liverpool Tuberculosis Scheme. The rare combination of sound medical knowledge and administrative ability which Dr. Hawksley possessed led those who best knew him to predict a brilliant and important career. Of his services to his country since war was declared little is known to those at home, but if his military duties were performed with the enthusiasm, tact, and efficiency which characterised his work as a civil servant, the loss to the army is as deplorable as to the city of Liverpool. His interests were many-sided, for besides the numerous committees of charitable organisations on which he served the Atmospheric Pollution Committee has reason to feel the loss of an enthusiastic worker. Admired by his acquaintances, he was loved by his friends, and of the latter he had many, for a charming disposition attracted those with whom he came in contact. All who knew him will deeply sympathise with his widow and two children in their tragic bereavement."

FREDERIC FRANCIS GERMAN, L.R.C.P., L.R.C.S. EDIN.,

CAPTAIN, ROYAL ARMY MEDICAL CORPS.

Captain Frederic Francis German died at his residence at Seaforth, Liverpool, early in April, at the age of 56. For over 30 years he was in practice at Seaforth, and took a keen interest in the life of the township. He had occupied the position of chairman of the urban district council and was a prominent Freemason. Captain German was a native

of Burslem, Staffordshire, and was educated at Liverpool University, subsequently proceeding to Edinburgh, where he qualified in 1881. He then settled at Seaforth, and at the time of his death was one of the oldest medical practitioners in the district, and was held in very great esteem, as was evidenced by the large numbers who attended his funeral, which was accompanied with full military honours. Captain German was medical officer of health of the Waterloo-with-Seaforth urban district council, physician to the Waterloo and District Hospital, county police surgeon, and medical officer of the Liverpool Overhead Railway Company. He was a keen Volunteer under the old system, and for some years held the rank of surgeon-captain in the Lancashire (Volunteer) Artillery. At the outbreak of war he was appointed surgeon in charge of the military hospital at Seaforth Barracks, and in June, 1915, was gazetted as temporary captain in the Royal Army Medical Corps. He leaves a widow, a son (a staff-sergeant in the Royal Field Artillery), and a daughter.

Medical News.

SOCIETY OF APOTHECARIES OF LONDON.—At examinations held recently the following candidates passed in the subjects indicated:—

Surgery.—H. Archer (Sections I. and II.), Bristol; E. V. Beaumont (Sections I. and II.), St. Mary's Hospital; M. J. Byrnes, Cork; E. N. Glover (Sections I. and II.), Guy's Hospital; and E. O. Morrison (Sections I. and II.), Cambridge and St. Mary's Hospital.

Medicine.—M. J. Byrnes, Cork; and M. Dwyer (Section II.), St. Thomas's Hospital.

Forensic Medicine.—J. S. Bhajiwalla, London Hospital; H. N. D. Richards, St. Mary's Hospital; G. G. Rigby, Manchester; C. Segal, Berne; M. B. M. Tweed, Guy's Hospital; and L. Zarchi, Petrograd and Royal Free Hospital.

Midwifery.—C. P. Barber, Charing Cross Hospital; T. F. Reason, St. Mary's Hospital; and I. H. Syed, Bombay and Manchester.

The Diploma of the Society was granted to the following candidates, entitling them to practise medicine, surgery, and midwifery:—E. V. Beaumont, M. J. Byrnes, and E. N. Glover.

UNIVERSITY OF GLASGOW.—At the graduation ceremony on April 25th the following degrees were conferred:—

Doctor of Medicine (M.D.).—Dagmar Florence Curjel.
Master of Surgery (Ch.M.).—Robert Buchanan Carslaw.

Among the University prizes and special class prizes gained were the following:—

Thesis for M.D.—Matthew Young, M.D., Bellahouston Gold Medal.
Research in Anatomy.—Matthew Young, M.D., Struthers Gold Medal and Prize of £20.
Chemistry.—John B. Sandford, George Roger Muirhead Prize of £2 5*s*.
Laryngology and Rhinology.—Kenneth J. T. Wilson, Asher Asher Gold Medal.
Physiological Physics.—William Napier, Arnott Prize of £25.
General Physics.—William L. Templeton, Arnott Prize of £15.

CENTRAL MIDWIVES BOARD.—At a meeting of the Central Midwives Board, held at Caxton House, Westminster, on April 13th, with Sir Francis H. Champneys in the chair, further correspondence was considered with Dr. E. J. Maclean, of Cardiff, with regard to the acceptance of the curriculum and system of training which he proposes to adopt in connexion with the Glamorgan County Free Midwifery Students as a compliance with the requirements of the new Rules C. 1 and 2. The Board decided that Dr. Maclean be informed that it appears to the Board that the course of instruction given by him (which the Board fully believes to be excellent) is given to women with a view to an examination to be held for the purpose of ascertaining whether they are or are not fit to be granted scholarships in midwifery. Such a course of instruction would be antecedent to any definite pupilage in midwifery, and could not therefore be considered as forming part of any midwifery curriculum. A letter was considered from Dr. W. E. Fothergill, one of the Board's examiners at the Liverpool and Manchester Centre, suggesting amendments to Rules C. 1 and 2 with a view to meeting the case of candidates who have had a three years' training in a public special hospital for women or a public special hospital for children. The Board decided that Dr. Fothergill be informed that the Board has already completed the revision of the Rules and has forwarded them to the Privy Council for approval. The matter is consequently out of the hands of the Board. A letter was considered from the county medical officer of health of Devon, calling the attention of the Board to an apparent case of "covering" an uncertified woman by a registered medical practitioner in the county. The Board decided that the papers in the case be forwarded to the General Medical Council with a request that they will take such action in the matter as may seem fit to them, and that, if so desired, the Board will undertake to appear as prosecutors in the case. A letter was considered from the secretary of the Association for Promoting the Training and Supply of Midwives, suggesting that the Board should apply to the Privy Council for power to require the surrender of the certificate of a deceased midwife. The Board decided that the Association for Promoting the Training and Supply of Midwives be informed that the new Rules are already in the hands of the Privy Council, and that the suggestion made by the association does not commend itself to the Board, inasmuch as it would be at variance with the custom relating to other certificates and diplomas, none of which, so far as the Board is aware, have to be surrendered on death. The Board feels sure that any request for special powers in the case of midwives would be refused. It is not the possession of a certificate but the presence of her name on the Roll which enables a woman to practise as a midwife.

A special meeting of the Board was held at Caxton House, Westminster, on April 14th, with Sir Francis Champneys in the chair, when a number of midwives were struck off the Roll for non-compliance with various Rules.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—Demonstrations of specimens in the Museum of the Royal College of Surgeons of England will be given in the theatre of the College by Mr. S. G. Shattock, the pathological curator, at 5 P.M. on the following days: Monday, May 1st, on Fractures; Monday, May 8th, on Foreign Bodies; and Monday, May 15th, on Results of Inflammation. The demonstrations are open to medical students and practitioners. First-aid and ambulance students desirous of attending will also be admitted.—The subject for the Triennial Prize to be awarded in 1918, is "The Development of the Hip-Joint and the Knee-Joint of Man." This prize consists of the John Hunter Medal executed in gold to the value of 50 guineas, or, at the option of the successful author of the dissertation, of the medal executed in bronze, with an honorarium of £50. The subject for the Jacksonian Prize for the present year (1916) is "Methods and Results of Transplantation of Bone in the Repair of Defects caused by Injury or Disease." The subject for the prize for 1917 is "The Causation, Diagnosis, and Treatment of Traumatic Aneurysm, including Arterio-Venous Aneurysm." The dissertations for the Jacksonian Prize for 1916 must be delivered at the College not later than 1 o'clock P.M. on Saturday, Dec. 30th, 1916.

POOR-LAW MEDICAL OFFICERS' ASSOCIATION OF ENGLAND AND WALES.—At the last meeting of the council of this association a letter was read from the Local Government Board in answer to an inquiry by the honorary secretary (Dr. Major Greenwood) as to whether drugs that had risen in price greatly during the war did not come under the description of "expensive medicines," and whether they should not be included among those that boards of guardians were required to furnish. The Board replied that, while they have recommended that "expensive medicines" should be supplied at the cost of boards of guardians, they have not issued any regulations on the subject, and that the arrangements to be made in individual cases would depend on the terms of the agreement between the medical officer and the guardians. The honorary secretary said that it was clear from this that the provision of "expensive medicines" was not compulsory on boards of guardians, and appeared to be only an act of grace on their part. That being so, they could not be compelled to provide the cost of drugs that had become expensive through the war. It would appear that the guardians generally throughout the country had for many years agreed to pay the cost of certain drugs, and by raising the salaries of medical officers in not a few cases during the war had practically met the additional cost of drugs due to the war. It seemed to him that no further pressure could be put on them to do more at the present time. The arrangements for the annual meeting were considered, when the council decided that it should be held during the first week of July, the particular day to be fixed later by the honorary secretary; only formal business was to be transacted, and there was to be no dinner. It was

also resolved that the next council meeting should take place an hour before the annual general meeting, and that both should be at the same place, and that, if possible, the office of the association at 9, Copthall-avenue, should be utilised for that purpose, as owing to the war the attendance was not likely to be very large.

THE LATE DR. WILLIAM ALLAN JAMIESON.—Dr. W. A. Jamieson, a late President of the Royal College of Physicians of Edinburgh, died at his residence, Charlotte-square, Edinburgh, on April 21st, aged 77. He received his medical education at Edinburgh University and at Vienna, graduating M.B. and C.M. Edin. with honours in 1865. In 1877 he took the M.D. of his University and the F.R.C.P. Edin. He was surgeon to the King's Body Guard in Scotland, the Royal Company of Archers, a Knight of Grace of the Order of St. John of Jerusalem in England, and held the Royal Household Jubilee medal of 1897 and the Coronation medal of 1911. Dr. Jamieson, who was an LL.D. of Edinburgh, was a well-known authority on skin diseases.

THE ROUTE OF THE ORIENT LINE STEAMERS.—The Orient Line to Australia announce that by direction of His Majesty's Government their steamers will, until further notice, proceed to and from Australia by way of the Cape of Good Hope, calling at Cape Town outwards and Durban and Cape Town homewards. The first sailing of this new service will be from London on June 2nd.

THE Wellcome Historical Medical Museum will be reopened on Wednesday next, May 3rd. A special exhibition of Japanese charms and amulets of medical interest, lent by Mr. W. L. Hildburgh, M.A., Ph.D., will be on view, and should prove of exceptional interest to students of medical folk-lore. The museum will be open from 10 A.M. to 6 P.M. daily, and from 10 A.M. to 1 P.M. on Saturdays, until further notice.

Vacancies.

For further information regarding each vacancy reference should be made to the advertisement (see Index).
When the application of a Belgian medical man would be considered the advertisers are requested to communicate with the Editor.

BIRMINGHAM AND MIDLAND EYE HOSPITAL, Church-street, Birmingham.—Resident Surgical Officer. Salary from £200 to £300 per annum, with board, residence, &c.

BOURNEMOUTH HOSPITAL FOR SICK AND WOUNDED, Boscombe.—House Surgeon for six months. Salary £125 per annum, with board, lodging, and washing.

BRIGHTON COUNTY BOROUGH ASYLUM, Haywards Heath.—Temporary Resident Assistant Medical Officer. Salary 25 guineas a month.

BRISTOL ROYAL INFIRMARY.—House Physicians and House Surgeons. Salary at rate of £120 per annum, with board, apartments, and laundry.

BURNLEY, VICTORIA HOSPITAL.—Female House Surgeon. Salary £160 per annum, with residence, board, and washing.

BUXTON, DERBYSHIRE, DEVONSHIRE HOSPITAL.—Assistant House Physician. Apartments, board, laundry, and salary as arranged.

CROYDON GENERAL HOSPITAL.—House Surgeon. Salary £200 per annum, with residence, board, and laundry.

DERBY, DERBYSHIRE ROYAL INFIRMARY.—House Physician and Casualty Officer. Salary £200 per annum, with board, residence, &c.

DORCHESTER, DORSET COUNTY COUNCIL.—Temporary Female Assistant Medical Officer of Health. Salary at rate of £300 per annum.

EAST END OF LONDON TUBERCULOSIS DISPENSARY.—Tuberculosis Officer. Salary £500 per annum.

FEDERATED MALAY STATES GOVERNMENT.—Female Medical Officer. Salary £350 per annum, with free quarters. CENTRAL LUNATIC ASYLUM: Assistant Superintendent. Salary £400 per annum, with free quarters.

GRANGE-OVER-SANDS, WESTMORLAND CONSUMPTION SANATORIUM AND HOME, Meathop.—Second Assistant. Salary £200 per annum, with apartments, board, and laundry.

GRAVESEND HOSPITAL.—House Surgeon. Salary at rate of £200 per annum, with board and residence.

HELLINGLY, EAST SUSSEX COUNTY ASYLUM.—Local Tenens Assistant Medical Officer for three weeks. Salary 6 guineas a week, with board, lodging, and washing.

LEEDS PUBLIC DISPENSARY.—Female Resident Medical Officer. Salary £130 per annum, with board, residence, and laundry.

MANCHESTER CHILDREN'S HOSPITAL, Pendlebury.—Two Female Resident Medical Officers, unmarried, for six months. Salary at rate of £100 per annum.

MANCHESTER NORTHERN HOSPITAL FOR WOMEN AND CHILDREN, Park-place, Cheetham Hill-road.—Female House Surgeon. Salary £120 per annum, with apartments and board.

NORTHAMPTON GENERAL HOSPITAL.—House Surgeon. Salary £150 per annum, with apartments, board, washing, and attendance.

PORTSMOUTH WORKHOUSE INFIRMARY, WORKHOUSE, AND CHILDREN'S HOME.—First Assistant Medical Officer. Salary £250 per annum, with apartments, rations, &c.

QUEEN'S HOSPITAL FOR CHILDREN, Hackney-road, Bethnal Green, E.—House Surgeons for six months. Salary £100 per annum, with board, residence, and washing.

ROCHESTER, ST. BARTHOLOMEW'S HOSPITAL, Kent.—Senior Resident House Surgeon. Salary at rate of £300 per annum.

ROYAL WESTMINSTER OPHTHALMIC HOSPITAL, King William-street, West Strand, W.C.—House Surgeon for six months Salary as arranged.

SALISBURY GENERAL INFIRMARY.—House Surgeon and Assistant House Surgeon, unmarried. Salary £150 and £100 per annum respectively, with apartments, board, lodging, and washing.

SHEFFIELD, JESSOP HOSPITAL FOR WOMEN.—Female Junior House Surgeon, unmarried. Salary £80 per annum, with board, residence, and laundry.

SHEFFIELD ROYAL INFIRMARY.—House Physician. Salary £120 per annum, with board and residence.

SOUTHAMPTON FREE EYE HOSPITAL.—House Surgeon. Salary £100 per annum, with board, lodging, and laundry.

VENTNOR, ISLE OF WIGHT, ROYAL NATIONAL HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST.—Assistant Resident Medical Officer.

WEST HAM AND EASTERN GENERAL HOSPITAL, Stratford, E.—House Physician.

Births, Marriages, and Deaths.

BIRTHS.

BALLANCE.—On April 21st, at All Saints' Green, Norwich, the wife of Lieutenant-Colonel H. A. Ballance, R.A.M.C. (T.), of a son.

FULLER.—On April 17th, at Milnthorpe, Westmorland, the wife of W. A. Fuller, M.R.C.S., L.R.C.P. Lond., of a son.

LUMSDEN.—On April 20th, at Lyme Regis, the wife of Dr. H. F. Lumsden, of a daughter.

WINTER.—On April 19th, at John o' Gaunt's House, Lincoln, the wife of Captain E. S. Winter, R.A.M.C. (T.), of a son.

MARRIAGES.

DARLINGTON—BATCHELOR.—On April 20th, at Grange-road Presbyterian Church, Birkenhead, Captain G. Hellyar Darlington, R.A.M.C., to Ida M., elder daughter of Captain J. W. Batchelor and the late Mrs. Batchelor, of Birkenhead.

DAVIES—EDMUNDS.—On April 18th, at Holy Trinity Church, Southport, Dr. Ll. E. Davies, to Mary Constance, daughter of the late Richard Edmunds, J.P., M.R.C.S., L.R.C.P., of Pontnewydd, near Newport, Mon.

DRURY—BROWNSWORD.—On April 19th, at St. Bartholomew-the-Great, London, Alan Nigel Drury, Lieutenant, R.A.M.C., to Daphne Marguerite, elder daughter of Mr. H. A. Brownsword and Mrs. Brownsword, of Rollesby Hall, Norfolk.

DEATHS.

HUMPHRY.—On April 16th, at Marlborough-terrace, Glasgow, Arthur Dumville Humphry, M.R.C.S., L.R.C.P. Lond., aged 49 years.

JAMIESON.—On April 21st, at Charlotte-square, Edinburgh, William Allan Jamieson, M.D. Edin., F.R.C.P. Edin., LL.D., aged 77 years.

N.B.—A fee of 5s. is charged for the Insertion of Notices of Births, Marriages, and Deaths.

BOOKS, ETC., RECEIVED.

BAILLIÈRE, J. B., ET FILS, Paris.
Les Fièvres Paratyphoïdes. Par le Dr. J. Carles, Professeur Agrégé à la Faculté de Médecine de Bordeaux. Price 1.50 fr.

BAILLIÈRE, TINDALL, AND COX, London.
Physiological Chemistry: A Text-book and Manual for Students. By Albert P. Mathews, Ph.D. Price 21s. net.
Orthopedic Surgery. By E. H. Bradford, M.D., and R. W. Lovett, M.D. Fifth edition. Price 15s. net.

Notes, Short Comments, and Answers to Correspondents.

AN ANCIENT TEXT BEARING ON VENEREAL DISEASE.

AMONG the thousands of Assyrian and Babylonian cuneiform written tablets translated many allude to disease. Their medical matter arises from their being incantations against various maladies and instructions in magical methods of cure. Many texts contain prayers for the prevention or mitigation of disease, whilst some narratives closely allied to the story of Job present a list of all known ailments. Complete as the list of Mesopotamian maladies has been made, no indication of venereal disease, and certainly no enumeration of symptoms allied to, or identical with, syphilis has been detected. A recently deciphered text, however, may indicate the prevalence of such cases. In a cuneiform tablet, No. VIII., of a series of magical formulæ and prayers known as the "Surpu Texts," a list is given of four grades of hierophants, or priestesses. The title of one series is read as SAL-NU-GIG, and Assyriologists have no doubt as to the meaning being: "Woman: not: sick"; also that it is equivalent to the Hebrew word of qadistu, a person dedicated to service in a sanctuary. Now these women, of which four grades are specified, were dedicated to the service of Ishtar (Mylitta) in temples of that deity, the three other grades being the high priestess and two classes of temple maidens, or nuns, who it is almost certain were virgins. The Sal-nu-gig, or females in good health, for the works or service of Ishtar (Ashtarte), the licentious goddess of the Semitic race, doubtless specifies the class of women spoken of by Herodotus, who in the temples of Mylitta in Babylon surrendered themselves to the embraces of male visitors to the shrines as a regular part of the temple ritual. That their title should be practically a certificate of freedom from disease may indirectly show that venereal complaints were known. Also, the many fragments we possess of "The Story of Ishtar," a goddess like Venus, who freely bestowed her charms, show that on occasion the acceptance of her advances proved very evil, and even fatal to her admirers. One of these, a shepherd named Ishullum, in the part of Ishtar's mythological story concerning her adventures with him, remonstrates with the fickle goddess in the following terms:—

> Me—what dost thou desire of me?
> Hath not my mother baked, have I not eaten,
> That I should eat loathsome and burning fare?

It may be that the title Sal-nu-gig only refers to freedom from functional, periodic disorders, or malformations of certain organs, but it seems rather too emphatic to mean merely this. It is to be hoped that further light will be thrown upon the subject by the finding of other texts.

NOTIFICATION FEES AND THE CERTIFICATE QUESTION.

To the Editor of THE LANCET.

SIR,—Referring to the communication which appeared in your issue of April 15th (p. 847), there is one aspect of this question which is of great importance, and that is the serious effect the reduction of the notification fee may have on the early notification of cases of pulmonary tuberculosis. Even with the present fee it is difficult to obtain early notification. Every medical officer of health knows from experience how many cases are not notified until late in the illness, and sometimes only when death is imminent, or has occurred. Instead, therefore, of reducing the fee, public policy calls for an increased fee so far as pulmonary tuberculosis is concerned, and suggests that the fee—say of 5*s.* at least—should be given for early *diagnosis* and not merely for notification. It would be fairly easy to make adequate provision to prevent abuse of such a measure, which is the only objection likely to be taken to it.—I am, Sir, yours faithfully,

Hartlepool, April 24th, 1916. GEORGE JUBB.

THE CAYMAN ISLANDS: A HEALTHY DEPENDENCY.

THE Blue-book of the Cayman Islands for 1914–15 has just been received at the Colonial Office. The islands in question—Grand Cayman, Cayman Brac, and Little Cayman, with a total area of 225 square miles—form a dependency of Jamaica, administered by a Commissioner, assisted by the "Justices and Vestry." In June, 1911, a census was taken, showing a total population of 5564—2322 white, 2211 coloured, and 1031 black. In 1915 there were 171 births, and the death-rate was 8 per 1000. The Commissioner describes the islands as "among the healthiest places in the world. There are no cases of illness attributable to climatic conditions. The weather is warm for the greater part of the year. The prevailing breeze is from the south-east from April until October, when the cool season begins, with a change of wind to the north and north-west in the early part of November. The average temperature in the hot months is 83° F. (morning), 89° (midday), and 86° (evening), and in the cool months 71°, 80°, and 74°." The report of the Government medical officer contains the following passages: "Acute tonsillitis has been frequent. ..... Indigestion and dyspepsia are widespread and attack all ages, even those of tender years. It is due to the excessive consumption of a carbohydrate or starchy diet in the form of the cassava and sweet potato. It being impossible to eliminate these from the every-day dietary, I have advised the people to boil their cassava longer, also to eat it younger, and to use the sweet potato boiled instead of roasted. ..... Eight cases of typhoid fever occurred during the year; all were of a mild type with the exception of one case which proved fatal. ..... Six cases of pulmonary tuberculosis or consumption have come under my notice, three of which were far advanced and have since died. There are, however, many other early cases. Here the smoke-fire question is an important one. The irritating nature of the smoke tends to aggravate the persistent cough so often present and is most injurious. Equally so is this the case in the disease known as bronchial asthma, cases of which are quite as numerous as digestive troubles. ..... Fish-poisoning requires mention. Eighteen cases have, to my knowledge, occurred in the past seven months. The period of incubation varies from 12 to 48 hours, and the onset in each case was sudden. The symptoms and duration are what one meets with in a typical case of ptomaine poisoning, and the illness is treated by me as such with most satisfactory results. The opinion held locally is that all fish caught inside the reef are poisonous. This I do not agree with, as I have reliable information to disprove it. Baracoota, goat-fish, and jack are the fish most commonly believed to be poisonous. In all seven of the cases at which I had the opportunity of being present, I obtained a definite history pointing to the baracoota being the source of infection; in my opinion it is probably due to a toxin developed in the liver of the fish and akin to that found in certain forms of shell-fish. ..... There is yet another type of fever found all over the island and known locally as five-day fever. This, in my opinion, is a mild form of relapsing fever transmitted by ticks. ..... On the whole the health of the islands is good."

THERAPY OF WHOOPING-COUGH.

To the Editor of THE LANCET.

SIR,—As you have remarked of whooping-cough in England in the annotation in THE LANCET of Jan. 29th, so it might be said of it in South Africa, "the disease is always with us," in European as well as native. In the European it is a milder affection than at home, while in the native it is a severer disease and often complicated by bronchitis and pneumonia. Viewing whooping-cough as a whole, it cannot be said that Dr. Benstz's array of drugs to which you refer quite accord with the modern principles of therapy. The toxic symptoms—e.g., sopor, puffed face, vomiting, want of appetite—would seem to contra-indicate codeine, morphia, bromide, &c. Here, as in other general infections, a general internal antiseptic is indicated. Up to the present no drug conforms more to this demand than benzol. It is not poisonous, and the manner in which it kills the ova in bilharzia may be accepted as proof of its germicidal power. In bilharzia and whooping-cough it is very soon evident that it destroys toxins. In both conditions toxic symptoms rapidly disappear, pallor disappears, appetite returns, and weakness and lethargy diminish.

In whooping-cough, no matter how severe the case, during the first 24 hours under the drug the attacks become less severe, while after four days' treatment the infection in ordinary cases becomes a negligible quantity except for hygienic observances. Toxic symptoms especially are controlled, natural sleep and appetite return, bronchitis subsides, and a case can often be rescued deep in pneumonia or with cerebral symptoms, complications which do not occur when the drug is used *de novo*. Benzol is the fixing agent in the organo-arsenic compound salvarsan, but judging from its action in bilharzia it must be supposed to have an independent harmful action on bacterial protoplasm. Benzol is an aromatic hydrocarbon and could be synthetised with iodine to produce further efficacy in this and other infectious diseases. It is not readily broken up in the system. It proceeds unchanged through the intestinal canal and is freely excreted through the lungs. Incidentally it may be mentioned uric acid is freely excreted under its use, as witness the crystals in the urine while it is being taken. The drug I find is best dispensed in mucilage.

I am, Sir, yours faithfully,

WM. ROBERTSON.

St. Mark's, Cape Province, South Africa, March 6th, 1916.

Tidworth.—The income tax paid in January last was for the year ending April 5th, 1916, and a liability remains for a 20 per cent. addition in July relating to the year ending as above, and not to the present year. The service emoluments will be included in the next return for assessment.

J. F. M.—The explanation probably is that by the particular method adopted in making the beverage a greater quantity of the oils was extracted. These have marked stimulating effects. There could be no fermentative change of the sugar, as all yeasts would be destroyed on bringing the fluid to boiling. Yeast is entirely killed at 60° C., and therefore at that point its fermenting power ceases.

Curious.—The note appeared in THE LANCET of Feb. 17th, 1912, p. 444. The drops are said to be made by boiling sulphur with linseed oil or turpentine or both. The small bottle is covered with a piece of parchment, which may be pierced to obtain the preparation in drops. They are taken on sugar. On water they float as dark brown globules of oil. The smell to some people suggests the objectionable one of burnt indiarubber.

F. C.—The surveyor would appear to have followed the usual course in income-tax procedure. It is the custom, where a new owner of a practice is the successor of the previous owner, to assess the new owner, not upon his own profits from the time of the change, but upon the average profits of the last three years of the practice to which he has succeeded. The newcomer will, of course, be entitled to a repayment of some portion of the tax if, at the end of the period of assessment, he finds that the profits have fallen short of the average referred to. The surveyor certainly might allow the financial year to end on Dec. 31st, especially as previously the accounts were made up to this date, and we do not appreciate his objection to this course.

COMMUNICATIONS not noticed in our present issue will receive attention in our next.

Medical Diary for the ensuing Week.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, May 2nd.

SURGERY: SUB-SECTION OF ORTHOPÆDICS (Hon. Secretaries—A. S. Blundell Bankart, E Rock Carling): at 5 P.M.

Annual General Meeting.—Election of Officers and Council for Session 1916-1917.

PATHOLOGY (Hon. Secretary—Gordon W. Goodhart): at 8.30 P.M.

Annual General Meeting.—Election of Officers and Council for Session 1916-1917.

Communications:

Dr. Andrewes: The Bacteriology of Eleven Cases of Cerebro-Spinal Fever.

Dr. J. A. Murray: A Transplantable Tumour of the Guinea-pig.

Dr. B. H. Spilsbury: Specimens Illustrating Toxic Hepatitis.

Mr. Shattock: (1) Some Points in connexion with the Vermiform Appendix; (2) Some Specimens Illustrating Gunshot.

Wednesday, May 3rd.

SURGERY (Hon. Secretaries—Raymond Johnson, V. Warren Low): at 5.30 P.M.

Annual General Meeting.—Election of Officers and Council for Session 1916-1917.

Thursday, May 4th.

OBSTETRICS AND GYNÆCOLOGY (Hon. Secretaries—Cuthbert Lockyer, H. Russell Andrews): at 8 P.M.

Annual General Meeting.—Election of Officers and Council for Session 1916-1917.

Short Communication:

Dr. Herbert Spencer: A Short Case of Primary Carcinoma of the Fallopian Tube.

Specimens:

Dr. Russell Andrews: Primary Carcinoma of the Fallopian Tube.

Dr. Cuthbert Lockyer: Early Tubal Carcinoma arising in the Displaced Epithelium of Nodular Salpingitis.

Papers:

Dr. Henry Briggs: Unilateral Solid Primary Adenoma of the Ovary.

Mr. John D. Malcolm: Second Case of Pneumo-peritoneum; Release of Gas; Recovery.

Friday, May 5th.

LARYNGOLOGY (Hon. Secretaries—Cecil I. Graham, Frank A. Rose): at 5 P.M.

Annual General Meeting.—Election of Officers and Council for Session 1916-1917.

Discussion.

ASSURANCE MEDICAL SOCIETY AND MEDICO-LEGAL SOCIETY (CONJOINT MEETING), House of the Royal Society of Medicine, 1, Wimpole street, W.

WEDNESDAY.—5.30 P.M., Paper:—Sir John Collie: The Effects of Recent Legislation upon Sickness and Accident Claims.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY, West London Hospital, Hammersmith-road, W.

FRIDAY.—8.30 P.M., Meeting.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.

Course of Lectures on the Anatomy of the Human Body, for First-aid and Ambulance Students (open to all members of ambulance companies and first-aid classes):—

WEDNESDAY AND FRIDAY.—5.30 P.M., Prof. A. Keith. 4 P.M. to 7 P.M., Exhibition of Anatomical Preparations and Specimens in the Theatre on lecture days, and between 10 A.M. and 5 P.M. in the Hall of the Museum on the following day.

POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.

MONDAY.—2 P.M., Medical and Surgical Clinics. X Rays. Mr. Gray: Operations. Mr. B. Harman: Diseases of the Eye. Dr. Simson: Diseases of Women.

TUESDAY.—2 P.M., Medical and Surgical Clinics. X Rays. Mr. Addison: Operations. Dr. Banks Davis: Diseases of the Throat, Nose, and Ear. Dr. Pernet: Diseases of the Skin.

WEDNESDAY.—10 A.M., Dr. Saunders: Diseases of Children. Dr. Banks Davis: Operations of the Throat, Nose, and Ear. 2 P.M., Medical and Surgical Clinics. X Rays. Mr. Pardoe: Operations. Dr. Simson: Diseases of Women.

THURSDAY.—2 P.M., Medical and Surgical Clinics. X Rays. Mr. Gray: Operations. Mr. B. Harman: Diseases of the Eye.

FRIDAY.—10 A.M., Dr. Simson: Gynæcological Operations. 2 P.M., Medical and Surgical Clinics. X Rays. Mr. Addison: Operations. Dr. Banks Davis: Diseases of the Throat, Nose, and Ear. Dr. Pernet: Diseases of the Skin.

SATURDAY.—10 A.M., Dr. Saunders: Diseases of Children. Dr. Banks Davis: Operations of the Throat, Nose, and Ear. Mr. B. Harman: Eye Operations. 2 P.M., Medical and Surgical Clinics. X Rays. Mr. Pardoe: Operations.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY.—Clinics:—10.30 A.M., Surgical Out-patients (Mr. B. Gillespie). 2.30 P.M., Medical Out-patients (Dr. T. R. Whipham); Gynæcological Out-patients (Dr. Banister). 3 P.M., Medical In-patients (Dr. R. M. Leslie).

TUESDAY.—2.30 P.M., Surgical Operations (Mr. Carson). Clinics:—Medical Out-patients (Dr. A. G. Auld); Surgical Out-patients (Mr. Howell Evans); Nose, Throat, and Ear Out-patients (Mr. C. H. Hayton). Radiography (Dr. Metcalfe). 3.30 P.M., Medical In-patients (Dr. A. J. Whiting).

WEDNESDAY.—Clinics:—2.30 P.M., Throat Operations (Mr. C. H. Hayton). Children Out-patients (Dr. T. R. Whipham); Eye Out-patients (Mr. R. P. Brooks); Skin Out-patients (Dr. H. W. Barber). 5.30 P.M., Eye Operations (Mr. R. P. Brooks).

THURSDAY.—2.30 P.M., Gynæcological Operations (Dr. A. E. Giles). Clinics:—Medical Out-patients (Dr. A. J. Whiting); Surgical Out-patients (Mr. Carson); Radiography (Dr. Metcalfe). 3 P.M., Medical In-patients (Dr. R. M. Leslie).

FRIDAY.—2.30 P.M., Surgical Operations (Mr. Howell Evans). Clinics:—Medical Out-patients (Dr. A. G. Auld); Surgical Out-patients (Mr. B. Gillespie); Eye Out-patients (Mr. R. P. Brooks).

THE THROAT HOSPITAL, Golden-square, W.

MONDAY.—5.15 P.M., Special Demonstration of Selected Cases.

THURSDAY.—5.15 P.M., Clinical Lecture.

For further particulars of the above Lectures, &c., see Advertisement Pages.

The following magazines, journals, &c., have been received:—British Journal of Dental Science, London Hospital Gazette, Guy's Hospital Gazette, St. Mary's Hospital Gazette, Magazine of the London (Royal Free Hospital) School of Medicine for Women, Medico-Legal Journal, Annales de Médecine, Archives de Médecine et de Pharmacie Militaires, Proctologist and Gastroenterologist, Journal of Surgery, Medical Times, Revista Medica del Uruguay, New York Medical Times, Malaria e Malattie del Paesi Caldi, British Dental Journal, Quarterly Journal of Microscopical Science, Medical Chronicle, Bulletin de l'Office International d'Hygiène Publique, Medical Officer.

EDITORIAL NOTICES.

IT is most important that communications relating to the Editorial business of THE LANCET should be addressed *exclusively* "TO THE EDITOR," and not in any case to any gentleman who may be supposed to be connected with the Editorial staff. It is urgently necessary that attention should be given to this notice.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this office.

Lectures, original articles, and reports should be written on one side of the paper only, *and when accompanied by blocks it is requested that the name of the author, and if possible of the article, should be written on the blocks to facilitate identification.*

Letters, whether intended for insertion or for private information, must be authenticated by the names and addresses of their writers—not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or news paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale, and advertising departments of THE LANCET should be addressed "To the Manager."

We cannot undertake to return MSS. not used.

MANAGER'S NOTICES.

ALTERATION OF INLAND SUBSCRIPTION RATES.

OWING to the alteration in the Inland Newspaper Postal rate, the postage on each copy of THE LANCET will in future be 1*d.*, and sometimes 1½*d.*

The revised Inland Subscription rates are:—

One Year	£1 3 3
Six Months	0 13 8
Three Months	0 7 0

The rates for the Colonies and Abroad (thin paper edition) will be as usual:—

One Year	£1 5 0
Six Months	0 14 0
Three Months	0 7 0

Subscriptions (which may commence at any time) are payable in advance. Cheques and Post Office Orders (crossed "London County and Westminster Bank, Covent Garden Branch") should be made payable to the Manager, Mr. CHARLES GOOD, THE LANCET Offices, 423, Strand, London, W.C.

ADVERTISEMENT RATES.

The Milroy Lectures
ON
INFANTILE MORTALITY AND THE RELATIVE PRACTICAL VALUE OF MEASURES DIRECTED TO ITS PREVENTION.

Delivered before the Royal College of Physicians of London

BY S. G. MOORE, M.D. VICT., D.P.H. ENG. CONJ.,
MEDICAL OFFICER OF HEALTH AND LECTURER IN PUBLIC HYGIENE AND SANITATION, TECHNICAL COLLEGE, COUNTY BOROUGH OF HUDDERSFIELD.

LECTURE III.[1]

Delivered on March 16th.

THE RELATIVE PRACTICAL VALUE OF MEASURES AGAINST INFANT MORTALITY.

MR. PRESIDENT AND GENTLEMEN,—When one is faced with the task of framing an estimate of values which involves comparisons, it is desirable to establish a basis, or criterion, if any practical result is to be attained. Happily for our present purpose we have such a standard in the work of M. Morel de Villiers. I will proceed to give an account thereof.

THE WORK OF MOREL DE VILLIERS AT VILLIERS-LE-DUC.

During my early inquiries into the subject I saw a statement in a medical paper to the effect that at Villiers-le-Duc, a Commune of the French Midi, the infant mortality figure had been zero for ten years. I did not believe the statement. It was incredible. Yet I wrote to the French Academy of Medicine and inquired if they had any information on the subject. With the customary courtesy of our neighbours and gallant Allies, the Academy sent me a very full and complete answer confirming the fact, not merely by affirmation, but also by means of a print of a report to the Academy made by a special Commissioner, with the additional facts that during the same period no mother had died in child-bed, and at the date of the report all were *vivant et vigoureux*. Apparently the French Academy of Medicine had felt some difficulty in accepting so startling and important a statement.

So far as I am aware no translation of this report has been published in this country, except in my Report on Infant Mortality to the Huddersfield Sanitary Authority, the fourth edition of which is now out of print. There it is set forth in detail. It was my intention originally to embody it completely in these lectures, but because of the restriction imposed by time, and because it goes into great detail I will not do so. The actual regulations which achieved so perfect a result, however, must be set forth, and I will add certain of the more outstanding comments of the reporter, both translated into English:—

Regulations.

The Mayor of Villiers-le-Duc, considering that the municipal authorities have the duty of endeavouring to stop the depopulation of the country by taking the measures necessary to prevent birth mortality and any child being stillborn, and to do away with infantile mortality, the municipal council orders as follows:—

Article I.—Every woman with child, whether married or not, having her home in the village, and not in possession of sufficient means to allow her to take upon herself the expense of the measures necessary to secure, as far as possible, not only her own life, but also that of the child about to be born, shall have the right to require the help of the village authority.

Article II.—In order to take advantage of this favour she must declare her condition at the office of the Mayor, before the seventh month, and she shall at the same time indicate by what midwife she wishes to be attended. The midwife named shall be requested by the official head of the village to visit the woman with child in order to ascertain for herself that there is present neither albuminuria nor dystocia either of the child or of the mother, nor dangerous presentation. For this visit there shall be allowed to the midwife a sum of (5 francs) 4*s*. 2*d*. out of the fund opened in the village for free medical aid, and without any share of liability on the State or on the department.

Article III.—In case the midwife, after this examination, shall consider that it is necessary to call in a medical man, she must at once notify the municipal authority without giving the reason for the notice. The authority shall then request a medical man, at the choice of the woman with child, to take the measures necessary to bring about the confinement successfully. The fees of the medical man shall be secured on the credit of the free medical aid fund without any liability on the State or department.

Article IV.—Every woman who is assisted by the Commune at her confinement shall receive a grant of 10*d*. per day during six days (not counting the day of her confinement) if she remains in bed. This grant shall be paid to her at the end of six days. If the woman gets up before the time fixed the grant shall be refused. The cost of this shall be defrayed from the free medical aid fund without liability on the State or the department.

Article V.—Every woman who takes in a child to nurse, if she does not feed it at the breast, or if she feeds it partly at the breast and partly otherwise, shall be bound to provide herself with an apparatus to sterilise the milk, and shall follow out, for the feeding of the child, the written instructions which will be supplied to her by the municipality. She shall, on every occasion, when required by the municipality or by the visiting doctors, produce the sterilising apparatus, the feeding bottles, full or empty, the teats, and other accessories, in such a way that it will be possible to ascertain that they are in good condition.

Article VI.—All the infants placed out to nurse shall be weighed every fortnight on the communal baby-weighing machine either at the office of the Commune, if time permit, or at the home of the child. The increase of weight shall be noted on a slip kept separately for each child, and preserved at the office of the Commune

Article VII.—Every nurse-child brought up at the breast or on the bottle who may be attacked by any illness, especially by diarrhœa, vomiting, or respiratory troubles, must be notified to the municipality with a maximum delay of not more than 24 hours from the first appearance of the illness.

Article VIII.—In case nurses who have charge of the infants do not conform to the regulations in Articles 5, 6, and 7 above given, the certificate notifying their qualifications may be withdrawn from them eight days after the notification has been received without effect.

Article IX.—An apparatus for sterilising milk and exchangeable parts of the apparatus shall be placed at the office of the authority for disposal to the nurses, who may purchase them at a reduced price. The mothers who nurse their own children, and who are known to be in a state of poverty, shall be able to obtain on loan, without charge, a sterilising apparatus which they shall return to the office after the weaning of the child.

Article X.—Every nurse bringing up her own child, or a child entrusted to her, whether at the breast or by bottle, who shall produce the child in a good state of health at the age of one year, shall have the right to a grant of 2*s*. per month dating from the time when the child was begun to be nursed by her, up to the time when the child shall have reached the age of one year.

Ordered at Villiers-le-Duc.

THE MAYOR DE VILLIERS.

Report of Special Commissioner to French Academy of Medicine.

Wishing to have incontestable official documents, I wrote to M. Morel de Villiers, to ask him a certain number of questions for information. On Feb. 12th I received the following letters:—

DEAR PROFESSOR,—I have the honour to forward to you the documents you have asked me to send. The information which they contain is strictly accurate. It has been taken from our official records, and the records contained in the Archives of the Commune of Villiers-le-Duc. In accordance with your instructions, I have set out by our Mayoral Secretary (who is our schoolmaster) a table of the infantile mortality from birth to one year old in Villiers-le-Duc during a century from 1804 to 1903.

MOREL DE VILLIERS.

This table proves not only the truth of the assertions contained in the note of M. Morel de Villiers, but also that the real effects are even better than the results published. In fact the maximum and the minimum rates of infantile mortality as stated in the note are for the first nine decennial periods from 28 per 100 to 13 per 100, whereas in reality they are from 30 per 100 to 15 per 100. As for the infantile mortality during the last decennial period (1893 to 1903) it is simply zero.

In a careful reading of the figures contained in this table it is easy to make one note that is exceedingly interesting. There is shown, in fact, a sudden fall in the percentage of mortality from 1854 to 1863. Whilst up to that time the percentage has been almost regular since the beginning to the century (20·9, 22, 26·9, 25·6, 23·4), it falls all at once of 15 per 100 from 1854 to 1863.

[1] Lectures I. and II. were published in THE LANCET of April 22nd (p. 849) and 29th (p. 895), 1916, respectively.

The cause of this diminution of infantile mortality does not seem to me in any way a matter of doubt, and I entirely agree with the opinion of M. Morel de Villiers, who tells me: "I attribute this result to the fact that at this time my father was made mayor of the village. He knew nothing whatever of medicine, but he was very much interested in questions of public health. He was interested in children and distributed *layettes* for them, &c." The father of M. Morel de Villiers died in 1866, and his two successors in the mayoralty—excellent in other respects, but having neither his leisure nor his intellectual culture—took no interest in the babies, and then the infantile mortality went up again and soon reached 30 per 100.

In 1884 M. Morel de Villiers, the son, our actual colleague, was appointed mayor. At this time he was not acquainted with the simplest principles of medicine. He said to me, "As an officer I had learnt the art of killing, but not that of healing. I simply applied the principles of my father, and I attained the same results and almost in the same proportions." As a matter of fact, the infantile mortality was 15 per 100 from 1854 to 1863, and was 15·4 per 100 from 1884 to 1893. He studied medicine and took the M.D. for the purpose of this work.

To the table which I have just briefly analysed, M. Morel de Villiers has added another table which is not less interesting, which I ought to make known to the Academy. It is the table of the alterations of the population and of the average length of life during a century (1803 to 1903) in the village of Villiers-le-Duc. In spite of the exceptional importance attaching to the increase in the average duration of life in Villiers-le-Duc since the commencement of the century, and especially from 1884 to 1903 (34 years and 2 months in 1804), (66 years and 6 months in 1903), I confine myself to the subject in hand, and I will only call your attention to a single column of this table, which is concerned with the rate in relation to stillborn children.

This column shows, in fact, that from 1804 to 1878 there were 43 children stillborn, whilst there have been only two from 1878 to 1903. There has only been one child stillborn for 15 years. The death of this child, caused by the want of timely medical assistance, has made our friend take a special precaution. He has ordered the midwives to call in a doctor on every occasion where confinement is not brought to an end within 24 hours. This last measure just completes the admirable work organised by medical assistance at Villiers-le-Duc.

All the facts clearly impress upon us how necessary and essential it is to have the union, *the combined strength of both the officials of the administration and the representatives of the medical profession*. Isolated, their efforts, however good their intentions and wishes, will be fruitless and ineffective, but combined their effects will be all powerful. However, it is not always so, unfortunately.

Essential Features of Foregoing Regulations.

Let us consider what are the essential features of these regulations, which gave a perfect result. 1. They are *orders* to the people concerned to do certain things, and not merely recommendations or advice. 2. *Every* mother with child has the *right* to *adequate* assistance in childbearing. 3. She is required to notify pregnancy. 4. The midwives are *required* to ascertain that the pregnancy is normal, and if it be not so to notify the fact to the authority. For this service the midwife is paid out of public funds. 5. The authority then pays a doctor, *whom the mother chooses*, to take measures to bring about a satisfactory delivery. 6. A continuous supervision of and provision for the infant by the authority. 7. They are complete; they deal with *all* mothers and infants. It is worthy of note that in one of the most democratic countries in the world—a Republic, whose watchwords include "Liberty" and "Equality"—these things are *ordered* to be done. That the orders were obeyed is vouched for by the result.

My propositions in 1904 for the notification of births and of pregnancy were met with surprise. The former with some opposition on the part of the public and (I regret to have to say it) with a great deal on the part of medical men, while the latter seemed so ridiculous to the authorities that I quite failed to obtain for it any serious consideration. To-day, even this "ridiculous thing" lies within the "region of practical politics," and the notification of births is universal and compulsory throughout England and Wales.

Considerations based on these facts encourage me in setting forth the relative importance of work against infant and maternal mortality to take Morel de Villiers's regulations as a standard and compare various other "œuvres" with them. Their success appears to warrant the statement that they are the best standards extant; more than that, they approach perfection if we may judge by results. And what better criterion?

It is to be borne in mind that Villiers-le-Duc is a small place, the life there is that of a simple rural village, that the numbers concerned are small, and that the conditions in large urban communities are different; that these present degradation of living, drunkenness and other forms of vice, degrees of poverty, and so forth, which must preclude the hope of similar results, however effectively the measures of de Villiers may be applied. When we remember that the infant mortality figure for the children of medical men is 40 in this country, it at once becomes manifest that there are factors in the problem which make it clear that the results at Villiers-le-Duc are not within our reach.

Yet, on the other hand, let us not flinch from giving them their due weight. Let us not flinch from facing and attempting to overcome difficulties from whatever cause arising. We know that ignorance stands in the way. We can dissipate that. Apathy will disappear once it be realised that there is a stark need in the interest of the British race for the conservation of infant life. Vested interests present a more formidable obstacle, but by enlightenment of the general public and steady, tactful, diplomatic pressure this may be largely removed. Suspicion and jealousy need only to be met with frankness and friendliness to be won to the side of the good work.

When it was established that there had not been any exaggeration in the statement "that for the space of ten years no infant born at Villiers-le-Duc had died," the methods of the mayor of that commune received very careful scrutiny and consideration, of course. But among the many excellent—in fact, one is almost constrained to say perfect—recommendations there was one, which although I caused it to be printed in capitals in my report, did not reach its full signification in my mind until quite recently. It is contained in the closing words of the report to the French Academy of Medicine. They are worthy of reproduction:—

All the facts clearly impress upon us how necessary and essential it is to have the union, *the combined strength of both the officials of the administration and the representatives of the medical profession*. Isolated, their efforts, however good their intentions and wishes, will be fruitless and ineffective, but combined their efforts will be all-powerful. However, it is not always so, unfortunately.

The fact stated is so obvious that the tendency is to take it for granted, yet too much importance cannot be attached to the plain obvious necessity of obtaining, if it be at all possible to do so, the cordial and active coöperation of the family doctor with the public authorities in this work. Unfortunately the Notification of Births Act came at a time when the medical profession was not without just and proper cause of complaint. It were as unwise as unhappy to revive the unpleasantness, but every medical man will be able to think of one or more actions of the Government in respect of which the medical profession considered that it had reason to feel aggrieved. I believe that it was the result of this state of affairs rather than by reason of any intrinsic characteristics of the Notification of Births clause which led to an unfavourable reception thereof by many of our representatives. Be that as it may, I am happy to be able to say that there has not been any friction in the matter at Huddersfield. Certain medical gentlemen approved of the Act and notified births; others did not approve of the Act and did not notify births.

NOTIFICATION OF BIRTHS IN HUDDERSFIELD.

I will now exhibit a slide or two which will show the progress of the notification of births in Huddersfield, and also by whom these notifications have been made. (Tables I. and II.) These results were reported month by month to the sanitary authority, and, of course, they were regarded with very great satisfaction. There has never arisen a single case where a prosecution under the Notification of Births clause has even been in contemplation. The onus of notifying falls in the first place on the father of the child. It is to him we look, and from him we require an explanation in the event of omission. We found no antagonism whatever. The omissions result either from oversight, lack of knowledge of the requirements of the Act, or misunderstanding as to who was to forward the notification.

I have given some little prominence to this aspect of the work in Huddersfield, because I perceive with very great regret action on the part of certain associations, which I regard as mistaken. The work against infant mortality in Huddersfield has been the means of causing many more

people to consult the doctor than was the case prior to its inception. Furthermore, the importance of the newly born infant has been greatly increased in the public mind, with

the consequence that the mother and those who are associated with her and help her, share in her added dignity and importance—with satisfactory results in every direction.

INCOMPLETENESS OF PRESENT MEASURES.

We are now in a position to consider how far the measures in operation in this country, and which have already achieved a satisfactory measure of success, coincide with or diverge from the Morel de Villiers regulations. Unhappily there is but one coincidence, and the rest are divergences. The people are required to notify births. All the rest is more or less voluntary.

It is not established in this country that every mother has the right to adequate assistance in child-birth. It is true that there is the workhouse, but one need but name the association—I mean pauperism—to cause its exclusion from consideration in the minds of all who understand social life in England to-day. The resources of the Poor-law are not truly and willingly accorded as a right, but are yielded grudgingly and under degrading conditions. Neither midwives nor doctors have the duty explicitly laid upon them to ascertain that the pregnancy is normal, or in the presence of abnormality to notify the facts to anyone. An outstanding feature of the work of M. de Villiers is its completeness. From beginning to end, no distinction is made between one woman and another. It is not a question of married or not married, it is not a question of poverty or of riches. The welfare of the mother and her child is the sole consideration. This is as it should be.

When the Huddersfield sanitary authority commenced to work in this field, it was suggested that provision need only be made for visits to the babies born in the poorer districts, but after consideration provision was made for visiting every baby born in the borough. The wisdom of this decision soon was justified. The assistant medical officers entrusted with the visitation of the mothers and babies immediately after birth were given a discretion. They were allowed to omit visits if they thought fit. (I may mention incidentally that they were instructed to behave exactly as they would in social life, not to enter a house—any house, however humble—without an invitation, not to seat themselves unless bidden to do so, and so forth.) Embarking on this work they acted diffidently, as was natural. The result was that I received complaints, not that they had visited unduly or improperly, but asking: "Why was not my baby visited?" "How is it since a visit was paid by the lady doctor to Mrs. ——'s baby, that she did not visit mine?" I think it is plain that assistance in these matters should be tendered to all, without distinction, and where it is declined it should not be pressed. Provided, of course, that there is reason to believe that the mother is already furnished with adequate assistance in her need.

The work in this country is not in any sense complete. We have seen that about one-sixth of the babies born in this country year by year are dealt with by more or less voluntary associations, each working along its own lines, all doing excellent work, but without adequate, direct, authoritative guidance from the Government. Most significant of all is the fact that until quite recently no notice was taken of an unborn baby—none whatever. We do not even know how many have died prior to birth; we do not even yet know that essential fact from official records, although a careful estimate, made by a Fellow of this College—Dr. Amand Routh—gives the number at 100,000 per annum.

It appears to be quite a common-place, common-sense thing that the State should concern itself with the welfare of the mothers of the race. It does not seem to me to be a very singular or extraordinary project that when a woman is about to become a mother the authorities should take notice of the fact, with a view of helping her and with a view of ensuring that when her time of trial comes she shall have adequate assistance; that endeavours should be made beforehand to ascertain that all is well and to take what measures may be to remove dangers. Let me give an example showing the need for such help. I have recently established a system for the voluntary notification of pregnancy. Recently I received a notification of a woman in respect of whom the following report was submitted:—

Earliest anticipated date of confinement: March 15th, 1916.
Children: First healthy, second healthy. No miscarriages.
Present condition: Marked œdema of feet and legs; headache for past fortnight. Vision defective lately and occasional dizziness. Vomiting has been troublesome; palpitation frequently. (Eighteen months ago was under medical care for kidney trouble.)
Action taken: Advised to call in doctor and have help in the house at once. Danger of condition pointed out. Dr. E—— will be called in at once.
Condition of house: Clean, well lighted. To be revisited.
Revisited: 10th, 11th, 16th.
Report: Under doctor; much better.

Here is an example of what has been going on and still is going on. This woman, a wife, a mother of two young children, about to become the mother of a third, engages the services of a midwife. She is in imminent peril of her life. She does not know that to be the case. She regards the above symptoms as being inevitable to her condition. The midwife does not recognise the danger. How could she? She is not trained to do so. Medical training and

knowledge is needed for that. In the absence of the notification to the medical officer of health it is not too much to say that in all human probability the woman's life, and probably that of her baby also, would have been sacrificed. To-day there is every reasonable prospect that at least her confinement will be normal and she may live for years. Furthermore, there is no reason why the infant should not come into the world normally.[2]

I have heard the statement—in fact, it was made by a personage holding "high office"—that the notification of pregnancy is not to be thought of; that it would violate the privacy of family life and interfere with one of the holiest functions of humanity. With all respect, I affirm that only absence of information, nothing but lack of insight, can permit anyone to entertain such views. I can well imagine a medieval monk giving utterance, with much unction, to such ideas. In the days when all human afflictions were ascribed to the will of a benevolent deity, before knowledge had enabled men to serve themselves of natural resources, such ideas, opinions, and sentiments were normal and up to date, but surely they will not survive to-day! I have heard of objections from the professional point of view. But objection from this source can only be based on misconception. In every case, so far as Huddersfield is concerned at least, every condition calling for medical treatment will be referred to the family doctor.

It may be and probably will be claimed, and it certainly ought to be the case that the claim might be made with strict propriety, that where a woman has engaged the services of a duly qualified medical practitioner, she does not need any further help. I cannot speak to-day with any definite opinion, but some years ago I know that it was not the practice of the family doctor when engaged for a confinement to make any systematic precise effort to satisfy himself that his patient was normal, and that none of the conditions which from time to time arise and which are so disastrous in their results are present. If it be the case that things are altered nowadays, and that the family doctor does exercise these precautionary functions, then manifestly his patients are not in need of any further assistance; but if the old-fashioned state of affairs persists—and the death returns appear to indicate that this is in fact the case—then, in my judgment, the medical practitioner may very well welcome such aid as can be rendered by a colleague whose function and duty it is to do so, it always being well understood that every case should be referred for treatment to the medical man of the woman's choice.

ANTE-NATAL HYGIENE: PROCEDURE AT HUDDERSFIELD.

The following is an outline of procedure approved and adopted by the Huddersfield Sanitary Authority in the matter of ante-natal hygiene rendered possible by the notification of pregnancy:—

1. (*a*) *Notification of pregnancy* according to the scheme proposed by the medical officer of health in his report to the Health Committee. (*b*) *Visit* by assistant medical officer of health (female), who will consider the case in relation with the following matters.

2. *General.*—(*a*) *Hygiene of the home.*—Size in relation with number in house; light; air. Cleanliness; sanitary accommodation; separate lying-in chamber. (*b*) *Economic.*—Income available in relation to expenditure. (*c*) *Personal.*—Expectant mother and spouse. Healthy—(*a*) hereditarily, (*b*) constitutionally; clean; sober.

3. *Personal.*—(*a*) *Conceptions:* * Abortions—period, cause. Miscarriages—period, cause. Inter-relationship of each. Full term—Alive: Now living, healthy, unhealthy; died, age, cause. Stillborn: Cause. (*b*) *Type of labour:* Normal, difficult, instrumental. Complicated: Local—traumatisms, hæmorrhage, sepsis. General—convulsions, disease. (*c*) *Present health.* (*d*) *Past illnesses.*

* *Causes of abortion:* Cardiac, diabetic, nephritic; traumatic, displacements; abortifacients; lead, alcohol, specific disease.

4. *Examination of expectant mother.*—(*a*) *General:* Heart, lungs, gastro-intestinal, breasts. (*b*) *Abdominal:* Presentation, relationship of head to abdominal parietes (not p.v.). (*c*) *Pelvic measurement:* In case of need. (*d*) *Condition of urine:* Quantity, specific gravity, reaction, albumin, sugar. (*e*) *Investigation of abnormal reactions:* Urine and vaginal.

It would appear that an examination as suggested above will be best conducted at an ante-natal clinic.

5. *Advice.*—(*a*) *Nourishment:* Adequate, digestible, regular. (*b*) *Clothing:* Light, loose, warm, clean. (*c*) *Exercise, rest, sleep.* (*d*) *Personal hygiene:* Physical, mental. (*e*) *Provision for child:* Clothing, cradle.

6. *Assistance.*—(*a*) *Before confinement:* Food, if necessary. Medical advice, if necessary. (*b*) *At confinement:* Medical man or midwife engaged beforehand. Maternity bags, if necessary. (*c*) *Beds in isolation hospital* for cases of puerperal sepsis.

Disorders of Pregnancy.

In each case of abnormality it is proposed to communicate by letter with the general practitioner indicated by the woman, stating the facts and leaving the case to him.

A. *General.*—(1) albuminuria; (2) eclampsia; (3) pernicious vomiting. Refer to own doctor; rest; milk diet.

B. *Reflex disorders.*—(1) Ptyalism; (2) pruritus; (3) mental disturbances—sleeplessness and perversion of appetite. Refer to own doctor.

C. *Abnormal condition of gravid uterus.*—(1) Displacements, backwards, forwards; (2) anteflexion; (3) prolapse. Refer to own doctor. (1) Backward displacement: Refer to own doctor; avoid straining.

D. *Pressure symptoms.*—(1) Œdema—test heart, urine, &c.; (2) varicose veins; (3) hæmorrhoids. Refer to own doctor.

E. *Misplacement of ovum.*—(1) Ectopic gestation; (2) hæmorrhages; (3) miscarriages. Refer to own doctor.

Disorders associated with Pregnancy.

(A) 1. Acute eruptive fevers. 2. Specific diseases—S., T.B., Gon. 3. Cardiac diseases. 4. Renal diseases (nephritis, pyelitis). 5. Hepatic diseases (diabetes, jaundice). 6. Nervous diseases (chorea, insanity). 7. Pelvic diseases (carcinoma, tumours).

(B) Pelvic contractions.

ATTENDANCE AT PARTURITIONS OF MEDICAL MEN AND MIDWIVES.

The numbers of confinements attended by doctors and midwives have a bearing on the notification of pregnancy. Because whatever may be the view adopted as to the desirability or need for additional assistance to pregnant women who have engaged a qualified medical person to ensure a satisfactory delivery in childbirth none will be found to advance the opinion that a midwife has the training and knowledge requisite to recognise the dangers which may arise. In the Supplement to the Forty-fourth Report of the Local Government Board on "Maternal Mortality in connection with Child-bearing" it is shown that in two towns—St. Helens and Cardiff—all the births are attended by midwives, and that in eight others the percentages range from 75 to 83. In other places the percentage falls to 30. Let it be assumed roughly that about one-half of the total confinements in this country are attended by doctors and the other half by midwives.

Another factor should be considered. Since the Midwives Act came into operation there has been a tendency for women to seek the assistance of midwives rather than of the fully trained medical practitioner. (This was an inevitable result of the Act, but this is not the occasion to enter into a consideration of this point.) The experience in Huddersfield in this relation may be of interest. During 1907 21·74 per cent. of the total births were attended by midwives. In 1914 the rate had increased to 55·41 per cent. If this experience (I have not the means to ascertain whether this tendency to prefer the midwife to the doctor has extended to other places) continues, the desirability of securing the safety of the mother by notification of pregnancy becomes more pronounced.

EDUCATION.

It is better to teach the people how to live to-day than to teach them how people lived in ages that are dead. But there are difficulties in the way. At the International Conference on School Hygiene in London, I think it was the second, in the year 1907, after much advocacy of teaching in the above sense the President, the Marquis of Londonderry, explained that the need was recognised, but that teachers were wanting, and I understood him to express the intention of remedying the defect.

Manifestly the best direct method of improving the health of the nation in general, and of preventing the excess infant deaths, is to teach personal, domestic, and communal hygiene to the young. These might with propriety be regarded as essential subjects. I see nothing to prevent them being so dealt with that they would be equally educative as more abstruse and less useful subjects. But the *mortmain* still wields its power. Our educational system comes to us by direct succession from the priesthood. The soul, the mind, the spirit—whatever these things may be—must be regarded

[2] Since the foregoing was written the pregnancy has terminated satisfactorily and the mother and child are well.

—to the detriment of the body, notwithstanding the call for *mens sana in corpore sano*. I learned my "catechism" as a boy. Why not a catechism of health? Surely, if the all-important soul may be trained by question and answer, the less important body may be trained by similar means. The beneficial result on infant lives and on national health would be substantial if every child in the public elementary school were required to learn a simple catechism of hygiene such as any medical man would readily provide.

The promise—or quasi-promise—of the President of the Board of Education remains unfulfilled I believe. It may be that the needs arising out of the present war may lead to a realisation of the advisability of taking effective measures to teach the people how to live to-day. The following words of Herbert Spencer are so apposite that they might have been written à propos:—

If by some strange chance not a vestige of us descended to the remote future save a pile of our school books or some college examination papers, we may imagine how puzzled an antiquary of the period would be on finding in them no sign that the learners were ever likely to be parents. "This must have been the curriculum for the celibates," we may fancy him concluding. "I perceive here an elaborate preparation for many things, especially for reading the books of extinct nations and of co-existing nations (from which it seems clear that these people had very little worth reading in their tongue), but I find no reference whatever to the bringing up of children. They could not have been so absurd as to omit all training for this gravest of responsibilities. Evidently, then, this was the school course of one of their monastic orders."

Is it not an astonishing fact that though on the treatment of offspring depend their lives or deaths, and their moral welfare or ruin, yet not one word of instruction on the subject is ever given to those who by and by will be parents? Is it not monstrous that the fate of a new generation should be left to the chances of unreasoning custom, impulse, fancy—joined with the suggestions of ignorant nurses and the prejudiced counsel of grandmothers, mitigated as to one-sixth of the total by the efforts of voluntary associations animated by excellent intentions, but lacking the authority, which can only come from the Government?

CONCLUSION.

At the beginning of these lectures I referred to the importance of their subject. I desire that the last issue dealt with may be the same. Let it be that I avoid exaggeration; that I approach the matter with sane judgment, with care, and with accuracy. What is the subject in magnitude? How does it stand in relationship with national life? The number of human beings who are to replace the present farmers, artisans, weavers, bakers, butchers, merchants, shopkeepers, and defenders of their Fatherland, who are given to the nation by the nation's womanhood annually is more than 800,000. During the seven years 1906 to 1912 the number of infants who died was 736,682. So that in seven years all the national recruits of one year may be said to be obliterated, or nearly so.

That seems to be an important matter. But were these deaths inevitable? Let us consider. Let us try to answer clearly and in a manner which admits of no doubt. These infants died at the rate of 115 per 1000 births. In Norway, Sweden, New Zealand, Australia, in whole agricultural counties here in England, and in the better wards of our large towns, the rate falls below 80 per 1000. Furthermore, and I desire to give due prominence to this fact, in the better families among even the worst districts, the rate is equally low. But what is the very minimum fatality among infants? Morel de Villiers has answered "Zero." But among larger communities under the conditions of town life? Doctor's babies 40 per 1000, and almost all the professional classes under 50. But there can be no exact reply. Let me, therefore, err on the side of moderation, and assume that among these 736,682 babies who died between 1906 and 1912 all who were in excess of the rate of 80 per 1000 might have been saved. How many? The answer is 224,206.

Be it recognised I pray, that here is no trivial loss. The figure is substantial! Is it not so? But as a matter of fact, apart from sentiment, theory or desirability, can anything be done? Let one of your Fellows—Dr. Newsholme—answer. In his second report on the subject, folio 2, he states that the improved conditions have implied a saving of 185,772 lives in seven years, comparing 1906–1912 with the preceding seven years. It is easier to reduce a death-rate from 144 to 115 than from 115 to 80. True! But remember these results were obtained by non-coördinated effort—by work partly done by amateurs—and certainly without any special action on the part of the Central Government, without any initiative on its part. It remained to a relatively small provincial sanitary authority to display to the Government of the Nation the need to take steps to enable medical officers of health to become aware of the very existence of human beings who were known to be dying in excessive numbers—excess measured by tens of thousands per annum—from preventable and avoidable causes. Such being the case, what may we not hope when (partly as a result of the consequence of this gigantic and appalling war in which three continents are involved) the powers in Whitehall take hold of the reins and with wide open eyes, receptive mentality, and wise decision deal with the subject comprehensively.

These foregoing figures apply to infants dying after birth. As I have already stated, Dr. Routh gives good reason for the belief that 100,000 per annum die before birth. But surely these are inevitable. Not so! Means for the exact determination of *how many* of them are avoidable are not in existence, but we know that the causes of quite a considerable proportion are removable by skilled medical treatment. Here, again, is a loss of national moment.

Again, more than 3500 women die yearly in England and Wales from conditions resulting from child-bearing. After the numbers we have been considering three and a half thousand do not seem impressive, yet they are worthy of great attention because many result from preventable causes. Not only for themselves are these lives of vital interest to the community, but since each one is of child-bearing age the question arises, "How many more lives are lost to the State in this way?"

So much for the magnitude of the question. Let us turn for a moment to the ethical aspect of the subject. It need but be stated. A civilised country, at this very time engaged in a war against the two greatest military empires of all ages, which it joined because the territory of an ally was invaded and her freedom threatened, cannot permit, not by any possibility, "an army" of her own population to be destroyed annually. An "army," moreover, composed of individuals who, as I have tried to show, hold the right to protection from the State as well as from their parents, an "army" as helpless as innocent.

I have attempted to show (*a*) that the infant holds certain primal rights, as well from the State as from its parents; (*b*) that these rights are not effectively accorded to infants in this country at present; (*c*) that in consequence infants die who should live; (*d*) that the numbers who so die are of substantial magnitude—at least 30,000 per annum; (*e*) that work specially directed to the particular needs of infants has effected a reduction of fatality of more than 26,000 per annum[3]; (*f*) that this special work has been largely spontaneous, unregulated, of unequal efficiency, not applied to the total infant population, and without direct authoritative Government control; and (*g*) that the subject is of national importance.

I have given an account of work which achieved perfect success. This work was characterised by direct control, and engaged in its purview *all* mothers and *all* children both before and after birth. I therefore advocate similar action on the part of the British Government. I urge that the time is long over-passed for the continuance of "muddling through." A system in which, to our shame—not without encouragement and example from authority—we have taken a sort of indolent pride based upon the false and arrogant conception that our resources were so vast, our superiority so great, that *we* could afford to act negligently—to muddle—where it needs all the care, all the resources, all the power of organisation and of schematic, systematised effort on the part of other less favoured races or nations, even to avoid defeat, or disaster, or to obtain some success.

And, finally, I urge that the following things be done, *and done now*, not "after the war": Require the universal notification of pregnancy. Secure for *every* mother adequate provision of the means necessary for a satisfactory termination of her pregnancy. Make provision for and require the supervision of every infant born. Prohibit fraudulent

[3] Second Report on Infant Mortality, Local Government Board, 1912-13, fol. 2.

advertisements which destroy infants. Provide proper education.

I have tried to avoid meretricious appeals. I have endeavoured to pass by vulgar, popular references. It has been in my mind that only valid arguments based on facts and sober judgments are appropriate for submission to this College, in this ancient seat of learning. I have not been unmindful of the responsibility which attaches to the Milroy lectureship. Yet I feel keenly the undeserved pitiful sufferings of infants, and I recognise that sentiment does not commonly go hand-in-hand with pure, calm judgment. If I have been led away from the correct path I am sorry.

We have seen that the birth-rate tends to approximate to the death-rate. Large numbers permanently quit these shores every year. The population will soon be stationary and may decline. None can foresee or foretell the loss, immediate or remote, of the present fathers of the race inevitably resulting from the present great war. Here is no political matter. Here all parties can unite. It is—it must be—the plain immediate duty of every patriot, be he statesman or be he peasant, to do all that lies in his power to protect and foster the sole ultimate source of national strength—the Mother and the Child.

SOME FACTORS IN THE PATHOLOGY OF GAS-GANGRENE.

BY W. D'ESTE EMERY, M.D. LOND., M.R.C.S. ENG., L.R.C.P. LOND.,

CAPTAIN, R.A.M.C. (T.F.); DIRECTOR OF THE LABORATORIES, KING'S COLLEGE HOSPITAL.

(*With Illustrative Plate.*)

GAS-GANGRENE is one of the most interesting diseases that call for attention at the present time. Its occurrence after wounds of apparently trivial nature, its rapid and dramatic development, and, in many cases, its tragic issue, render it a matter of the utmost interest to the surgeon and of importance to the men in the field. And to the pathologist it is of the greatest interest, since it is an example of a disease which would appear to be caused by an organism of the most virulent description, but which, as a matter of fact, is due to one which is, under ordinary circumstances, almost non-pathogenic. The subject is of such interest and importance that I am led to publish the following, which is admittedly incomplete, being little more than a stating of the problem and a suggestion as to future lines of research. I am the less loth to do so in that a recent paper by Kenneth Taylor[1] dealing with the question leads to conclusions that I cannot accept.

Let us first state the question to be solved. A soldier is wounded, perhaps apparently but slightly. He is brought to the field ambulance, where nothing excites any special attention. At the casualty clearing station it is noticed that he looks ill, though he may feel very well. The limb is examined, and it may happen that it is found to be gangrenous already, tense, hard, yielding a peculiar note on percussion. Gas may escape from the wound, and, if so, it has a peculiar and disgusting odour. The patient himself also gives off a characteristic sickening odour, not strong, but repulsive in the extreme, which the sisters recognise as the "death smell." Amputation is performed above the gangrenous part of the limb, in apparently healthy tissues, but the disease reappears in the stump, spreads rapidly, and, perhaps, after another amputation, death follows with symptoms of profound toxæmia. This is one type. Many others occur. Thus the rapidity of the onset varies greatly. I have been informed by two or three good observers, regimental surgeons, that they have seen an abundant formation of gas within the tissues within two hours of the wound; and from a study of the cultural and pathogenic characters of the organism I can well believe it. I have myself seen death occur, with profoundly toxæmic symptoms, within 30 hours. Or the onset of the disease may be delayed long beyond this, and it may develop only at the base, or even in England. When this happens the disease is, I think, decidedly less rapid, less severe, and more amenable to treatment, than that which occurs early. Further, there is a great difference in regard to the amount of gas produced. Some cases, and I think on the whole the worst ones, have no gas in the tissues, or but little. In others there is much gas, under tension, so that the tissues crackle on palpation or when they are incised. Milder cases also occur, mere sloughing of flaps of skin, a single muscle, or piece of one, &c., and the disease remains localised to them, and has no tendency to general spread. Such cases show no toxæmia, or but little.

Looking only at the severe cases we should be led to expect that they were caused by a microbe of the utmost virulence. We might compare them, for example, with the rapid spread and profound toxic effects which occur in severe cases of anthrax or in post-mortem infections from cases of puerperal peritonitis. But we find that they are caused by a bacillus which is almost devoid of pathogenic powers. Let us glance briefly at some of the important features, from this point of view, of the bacillus in question, the B. aerogenes capsulatus, Welch's bacillus, or as it is more commonly and conveniently called nowadays, the bacillus perfringens.

It is an anaerobe, but not a very fastidious one. It will grow quite well in milk, the cream at the top acting as a seal to prevent the access of oxygen, and a pure culture can frequently be obtained by inoculating pus from a wound into sterile milk, boiling it and incubating for 12 or 24 hours. It forms spores, but only on certain media, especially those containing coagulable proteins; hence spores are present in pus. When growing in media containing glucose it forms an enormous amount of gas, but, on the other hand, it forms no spores. Under these circumstances it produces a great amount of organic acid, butyric, &c., and these are inimical to the further life of the bacillus, which dies out if not frequently subcultured. I have found the best medium by far for the cultivation of the bacillus, if rapid and profuse cultures are required, is glucose-broth to which pure chalk, in amount sufficient to form a layer ½ in. deep, is added; access of air is prevented by a layer of paraffin. The tubes are boiled shortly before use to expel any air that may have been absorbed. The purpose of the chalk is, of course, to neutralise any acid that may be produced; this it does very successfully, and if the cultures are shaken from time to time the broth will remain neutral or merely show a slight trace of acidity. In tubes like this growth takes place with extraordinary rapidity; this is a point on which I want to lay especial stress, and very large amounts of gas are given off. Cultures 18 hours old often contain 2000 million bacilli per cubic centimetre, and I have counted over 3000 million per c.c. after 8 hours incubation, the inoculated material being two or three drops of pus, the inoculated tube being boiled to kill all microbes other than spores. In serum, on the other hand, growth is slower, much less gas is produced, and spores are formed.

Let us turn to its pathogenic effects. Rabbits are very slightly susceptible. An injection of 2500 millions intravenously was followed by no appreciable ill-effects. A similar dose under the thin skin of the ear, a region well adapted for observing any slight lesion that might be produced, was equally inert. Guinea-pigs are more susceptible. A massive dose in the peritoneal cavity does not usually affect them, but after about 1000 millions subcutaneously (different cultures differ somewhat in their pathogenicity) there is usually rapid gangrene, followed by death in 24 hours or less.

The bacillus is equally non-pathogenic for man. It is a normal inhabitant of the alimentary canal, causing no harm. It is present at a certain stage in almost all wounds, causing no special pathogenic effects; indeed, I think the prognosis is decidedly better in the case, for example, of a suppurating wound of the knee-joint if this organism *alone* is present, than if a streptococcus or staphylococcus is present either by itself or in conjunction with B. perfringens. Nor are there evidences in these infections of its profoundly toxic effect. A patient (as, for example, one of Captain Fitzmaurice Kelly's, who made an excellent recovery with simple drainage) who has a knee-joint full of pus containing millions of bacilli may be perfectly fit and have a normal temperature. Still more striking are similar cases of hæmothorax, in which the blood in the chest contains these organisms in vast numbers, yet the patient is very fairly well—certainly he has none of the profound toxæmia present in typical and severe cases of gangrene.

[1] THE LANCET, Jan. 15th, 1916, p. 123.

So striking are these discrepancies that the question rises —Is the B. perfringens actually the cause of gas-gangrene? Is there not some other infection which we have overlooked? I think this question may be answered unhesitatingly in the negative. It appears to be true that the bacillus of malignant œdema occurs in some of these cases. I have never found it myself, and if it does occur it is certainly in numbers which are quite insignificant as compared with B. perfringens. Nor is it true that secondary infections—e.g., with streptococci—play an important part, as some have imagined. If you examine the pus from a wound which has led to the production of gas-gangrene, you will, it is true, often find streptococci sometimes in scanty numbers, sometimes more abundantly; but that is common in most wounds, and for every mixed infection with these two microbes which goes on to gangrene there are a hundred which do not. Further, if you examine the extending margin of the lesion you will find, at least usually, B. perfringens in vast numbers, and no other bacteria. This fact alone would be sufficient to prove the point, but taking it in conjunction with the pathogenic effect of a large dose subcutaneously in the guinea-pig, and with Welch's experiment (to be described subsequently) there can be no doubt that the organism we are discussing is the actual cause of the disease.

Before we can investigate the question why the bacillus produces spreading gangrene in some cases, we must find out, if we can, why it does not do so in others. In other words, what are the natural defences of the body? What happens when a patient becomes infected with the bacillus, and why do we not get gangrene in every case (and they are numerous enough) in which this happens? Firstly, the bacillus is killed by blood-serum and blood-plasma. Investigation on this point is by no means easy, and I have spent many fruitless hours in the attempt to elaborate a technique which would provide a simple and accurate method for the investigation of the bactericidal power of these fluids. The main difficulty arises from the fact that in an artificial culture of the bacillus many of the bacilli are dead, or at any rate non-viable on any medium that I have been able to devise; in some cases as many as 20,000 bacilli (as counted in the counting chamber) have failed to give a culture on any medium—and I have experimented with over 50. Further, the number of bacilli necessary to give a culture is exasperatingly inconstant. I have obtained a growth from three bacilli (by count and calculation) and a few days after, using the same stock, of the same age and on a similar medium, have not obtained one with 4000. As a result of this, in putting up a series of controls, using especial care, it may happen that a certain dilution gives a growth, whereas one five or ten times as strong gives none. This renders accurate work very difficult, but as the result of a considerable number of experiments I have no doubt that serum or plasma (the latter seems a little the more powerful) kills off the bacilli in fair numbers. The effect is intermediate between that of serum on typhoid bacilli and streptococci respectively. Typhoid bacilli are killed off in large numbers, so that the merest beginner in laboratory technique cannot fail to demonstrate the fact. Streptococci are killed only in small numbers and under the most favourable conditions, so that the demonstration of any bactericidal effect on these organisms is not easy and the results not convincing to a hostile critic. It is not difficult to convince anyone that serum does kill perfringens, but the number killed is not very great. Perhaps the effect is greater than it seems, the bactericidal substances being absorbed by the dead bacilli and so prevented from acting on the living ones. Perhaps, also, the capsule which surrounds the bacilli has some effect.

But the leucocytes constitute a very much more powerful defensive force. The bacilli are usually (sometimes there are exceptions) phagocyted very quickly in an ordinary opsonic mixture. More than this, they are rapidly destroyed. This comes out quite clearly in bactericidal experiments with "reconstituted blood"—that is, washed corpuscles such as are used in opsonic experiments mixed with fresh serum so as to form a fluid approximating in composition to circulating blood, but uncoagulable. Still more convincing perhaps is the study of opsonic preparations at varying intervals of time, and watching the gradual alteration, solution, and disappearance of the bacilli inside the leucocytes. In an ordinary phagocytic mixture of leucocytes, bacilli (washed to remove toxin), and serum, the degree of phagocytosis attains its maximum in one to three hours. After this the number of bacilli per leucocyte diminishes owing to bacteriolysis; this is proved by the number of "ghosts," some only perceptible with perfect staining and illumination, others visible without difficulty, which may be seen in the earlier stages of the process. Many of the bacilli lie in vacuoles, and the stages of their dissolution can be traced readily enough. Here is an example of the process, using the bacilli in emulsion just thick enough not to be killed altogether and incubating at the body temperature.

15 minutes. Average number of bacilli per leucocyte (polynuclears), 2·9. Bacilli clear cut, staining normally. A few appear to lie in vacuoles.

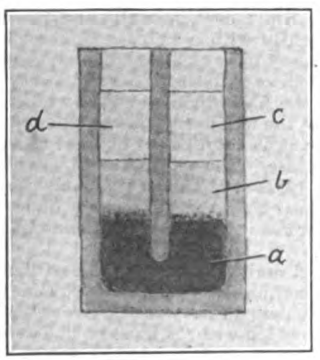
60 minutes. Bacilli per leucocyte, 3·5. Some of the bacilli lie in vacuoles. Rather more than half are changed—i.e., stain badly, or show a stained or unstained sheath. The extracellular bacilli all stain deeply. On staining by Gram's method the healthy-looking bacilli retain the stain, the "ghosts" do not.

3 hours. Average per leucocyte, 1·3. Partially dissolved bacilli nearly twice as numerous as normal forms.

5 hours. Here growth of the remaining bacilli had occurred, forming long forms within the leucocytes. The latter showed extensive degeneration, having evidently been acted on by a powerful toxin. They were markedly vacuolated, the protoplasm often being replaced by a foamy mass. The lobes of the nuclei were in many cases completely separated, as they often are in old pus, or definitely pyknotic. The leucocytes had clumped together (this is usually a sign of their death or injury) rendering counting impossible. There were many ghostly bacilli, but also numerous normal forms (some within vacuoles), and also the elongated threads mentioned above. The extracellular bacilli were all normal.

But the protective effect of the leucocytes is seen even more clearly when the question is studied in Wright's emigration tubes[2] or in the modification I have used, which consists of two pieces of a thin glass slide, just large enough to slip into the bucket of a centrifuge, kept together by a U-shaped piece of cardboard soaked in paraffin. The glass sides are applied whilst the paraffin is hot, and the apparatus clipped together and allowed to cool under pressure. This provides a thin cell about half an inch wide and an inch and a quarter long (for the centrifuge I have been using) and some half millimetre thick. To use it, the blood, or mixture of blood and microbes, &c., is run in at the top, which is open, and the apparatus centrifuged before clotting has taken place. The result is, as with the emigration tube, a thick layer of red corpuscles (mixed with some leucocytes), above which there is a narrow white zone (perfectly visible to the naked eye) of leucocytes, and again above this a layer of plasma, which soon clots and forms a delicate fibrinous reticulum, into which the leucocytes can climb with the greatest facility. To examine a preparation made in this way it is only necessary to immerse it in a saline solution containing 5 per cent. formalin and to raise the upper glass side slightly with a knife. The solution reaches the film of fibrin, scarcely causing any dislocation, and fixes it. After an hour or two the upper glass may be removed completely and the film which remains attached to the lower glass and to the cardboard sides stained as required? After staining it is allowed to dry and remains firmly adherent to the glass. The cardboard is cut away and the film mounted in balsam. This is the only way I know in which phagocytosis and the movements of leucocytes can be studied under conditions at all approximating to those which occur in life.

When a mixture of blood and a culture of B. perfringens (well mixed with a paraffined pipette on a paraffined slide) in suitable proportions is incubated a very instructive series of processes take place. To begin with, it must be understood that there is an even distribution of the bacilli throughout the film, for the centrifugalisation has not been long enough to drive them to the bottom. The conditions for growth are better the further we go down in the preparation, for here there is an approach to anaerobiosis, and as we should expect the growth (after five hours or so) gets more and more abundant as we go downward until a certain point is reached, when it ceases abruptly. This is perfectly visible to the naked eye in a methylene-blue stained specimen, and this provides a remarkable indication of the enormous rate of growth of this microbe. Below this there is a narrow



[2] THE LANCET, 1915, vol. ii., p. 787.

comparatively clear zone, then a very deeply stained band, which from its position just above the red corpuscles we can recognise as consisting of leucocytes.

A study of the preparation with the high power, and still more a comparison of preparations with varying doses of bacilli and incubated for various lengths of time, enable us to reconstitute clearly what takes place, and demonstrate beyond all doubt the defensive rôle of the leucocyte. In a specimen with a medium inoculation, such as I have described, incubated for about five hours we find that the leucocytes, which after the centrifugalisation formed a defined band with a sharp-cut upper edge, have begun to straggle out into the fibrin network above them, and have advanced about a millimetre above the point where they started. (Fig. 1 A) When we examine the zone they have traversed we find in the lower regions no bacteria at all; every one has been killed and dissolved, or, more probably, ingested and carried away by the leucocytes, doubtless undergoing intracellular digestion on its way. (Fig. 1 B.) Beyond this we see a few bacilli, some lying loose, but most in the cells, and still further out there is a zone where the leucocytes, which are abundant, are packed with bacilli; the cells themselves show signs of disintegration. (Fig. 1 C.) Beyond this again there is the felted mass of bacilli, growing unchecked, which we could discriminate with the naked eye. (Fig. 1 D.) Obviously, the leucocytes here are a perfect defence against infection. They creep out from the area from which they started, ingest the bacilli, and carry them along until they reach a region where the non-ingested bacilli have grown and have formed so much toxin that the new-comers are paralysed and subsequently killed. This process is a continuous one, the debateable ground between the serried masses of the bacilli on the one hand and the serried masses of the cells on the other being constantly traversed by leucocytes, and the invaders thus kept at their proper distance. (This constitutes an almost perfect imitation *in vitro* of the process of pus formation.) Even in the artificial conditions of the emigration chamber, where the supply of leucocytes is limited, and there is no arrangement for their nutrition and renewal, the defence is surprisingly strong, and even a heavy inoculation will be kept at bay for many hours, although the upper layer is an almost solid mass of bacilli. A study of such preparations leads to the confident belief that, given an abundant and constantly renewed influx of leucocytes, the infection, however great, can be kept at bay, and that a zone of such leucocytes would form, in the body, a perfect barrier against infection.

Next, how is this constant supply of leucocytes obtained? Obviously, the toxin, whatever it may be, of the bacillus has an attractive or chemotactic power over the leucocytes. This is susceptible of direct proof by means of a slight modification of the emigration chamber I have described. It consists of a cell which is made in the same way, but which is nearly divided into two vertical parts by means of a narrow band of paraffined cardboard running down the middle, but not quite reaching the lower wall of the cell. If this is half-filled with blood and centrifugalised the blood will divide itself into two columns, each exactly similar and each showing the alternation of red corpuscles, leucocytes, and plasma, the latter subsequently clotting, which has been already described. Various fluids can be superimposed on the top of the clots; they diffuse downwards, and their action on the leucocytes can be studied. This method is, as far as I know, the only one in which the action of drugs, &c., on the movements of leucocytes can be studied *in vitro*. As far as I can see it is devoid of fallacies. The action of two substances is compared on the self-same drop of blood under identical conditions. (Fig. 2).

FIG. 2.

Differential emigration chamber. a, Layer of red corpuscles. b, Fibrin layer, with stratum of leucocytes between it and the red corpuscles. c, d, Fluids the chemotactic effect of which is to be tested.

If we superimpose sterile broth on one column and a centrifugalised young culture, devoid of bacilli (neutralised if necessary), on the other, keep the preparation in the cold for an hour or two to allow penetration, and incubate it for a few hours, and then compare the amount of emigration, we shall see that it has progressed much further in a given time, that the leucocytes have moved further out from their original position in the column on which the culture fluid has acted. In other words, the toxin of B. perfringens, whatever it may be, has a positively chemotactic action on leucocytes. These facts give us, I think, a sufficient explanation why so few patients succumb to the infection, common as it is.

Let us now turn to the other question, and consider why, in the minority of cases, this defensive mechanism breaks down. To have a sufficient supply of leucocytes it is necessary to have a constant stream of fresh blood, and it is a well-recognised fact that nothing is so likely to lead to gangrene as any interference with the circulation. Laceration of the great vessels, pressure on them by a projectile or a piece of displaced bone, tight bandaging, &c., are always causes of danger, and to be avoided at all costs. In this connexion I should like to draw attention to a possible danger from the use of the tourniquet. Is it really necessary to use it at all, or in any but the rarest cases? Captain H. F. Marris, R.A.M.C.(T.C.), has informed me that in 1000 consecutive cases he only found it necessary to use it once, and this was in the earlier fighting, when, I should imagine, the amount of time for each case at the disposal of the regimental surgeon was much less than it is now, and the temptation to use the tourniquet correspondingly greater. Having regard to the enormous rapidity with which the bacillus of gangrene grows under favourable conditions, it appears to me to be a source of danger even when applied for a very short period. In a case in which the defensive power of the body and the dose of bacilli are evenly matched, even a short interference with the blood stream may turn the scale.

DESCRIPTION OF FIGURES IN ILLUSTRATIVE PLATE.

FIG. 1 A.—General view of an emigration chamber inoculated with a mixture of normal blood and B. perfringens, and incubated five hours.

FIG. 1 B.—A more magnified view of the leucocytic zone of the same preparation. Note the complete absence of bacilli. The leucocytes have emigrated from the compact layer they occupied at first.

FIG. 1 C.—The zone immediately above that last figured. In the lower area (which has been traversed by some leucocytes), no bacilli. In the upper portion, a few, mostly phagocyted by the leucocytes.

FIG. 1 D.—Zone just above the last, showing the enormous masses of bacteria. Some trace of phagocytosis can be seen in the lower part of the illustration, but the bacilli have grown out into masses, destroying the leucocytes.

FIG. 3 A.—Showing the emigration of the leucocytes in a differential emigration chamber (Fig. 2) in response to plain broth.

FIG. 3 B.—From the other limb of the same chamber, showing inhibition of emigration by the toxin of B. perfringens.

But this does not solve the difficulty. Admitting that the bacilli may grow well in dead or devascularised tissues, why does not the invasion stop when healthy tissues with a perfect blood-supply are reached? It does not, but spreads in them with a rapidity hardly equalled by any microbic infection. Kenneth Taylor, in the article already mentioned, suggests that the pressure of the gas generated in the tissues is usually, if not always, the most important part of the infection. "So it may be charged with the development of highly pathogenic possibilities in a usually rather innocent infection. It brings about: (*a*) the death of the tissues from the resulting anæmia produced by a pressure much higher than that of the circulating blood; (*b*) the actual mechanical fragmentation of the tissues, especially muscle; and (*c*) the mechanical scattering of the infection."

I disagree with this altogether, and for this reason: gangrene may occur, and the patient may die, without the formation of any gas in the tissues, and in many cases of severe disease there is but little, and none in the advancing edge. Taylor regards the disease especially as a muscle infection, but this is only because the gas is specially produced in those organs; the infection spreads equally in the subcutaneous tissues, which may often present enormous numbers of

FIG. 1A.

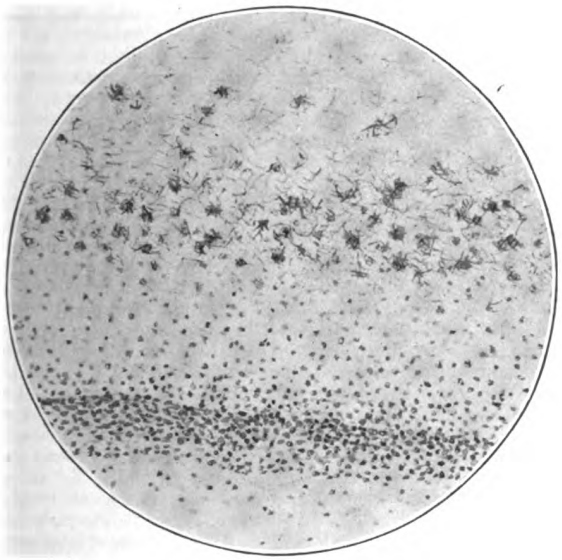


FIG. 1B.

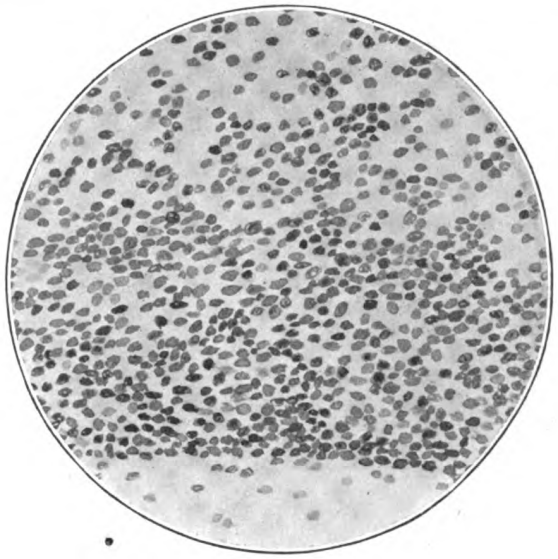

FIG. 1C.

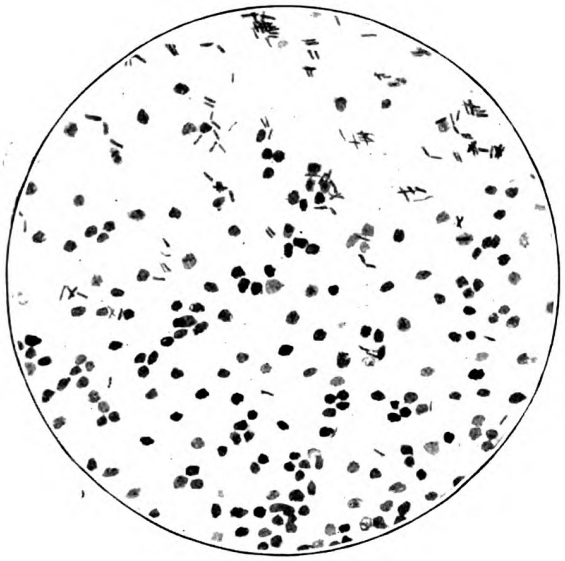

FIG. 1D.

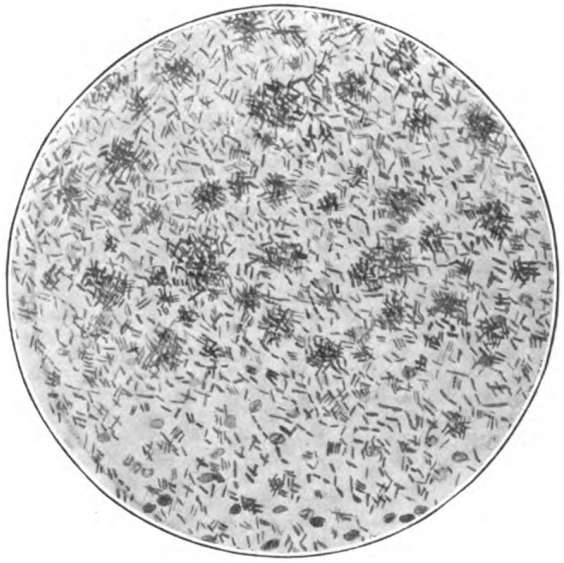

FIG. 3A.

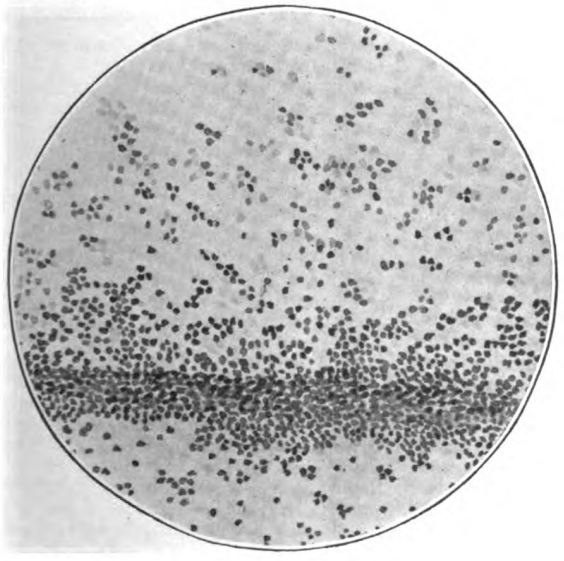

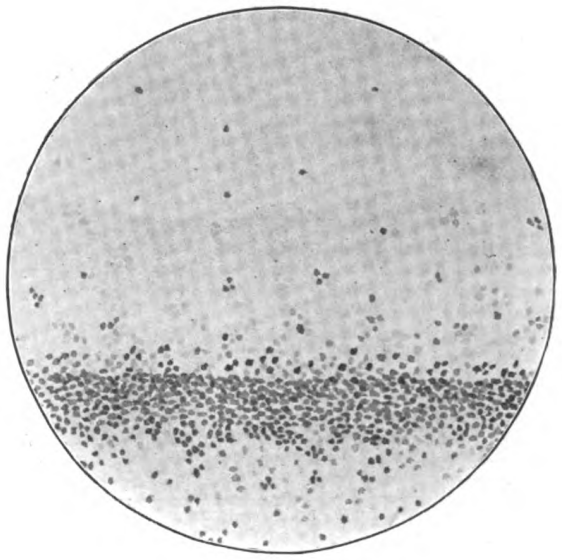

FIG. 3B.

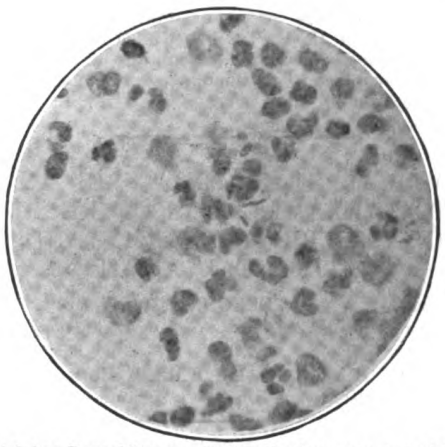
bacilli, though there is no gas whatever. The facts are easily explicable when we remember that sugar is necessary for the production of large amounts of gas; thus, if we inoculate a rabbit intravenously and immediately kill it and put it in an incubator at body temperature (Welch's experiment) we find that the bacilli grow in all parts of the body with amazing rapidity, but form gas first and most abundantly in the liver and kidney, regions rich in sugar. Sugar is also present in the muscles, and gas occurs in these regions, but not as early or as abundantly as in the viscera mentioned. The skin is poor in sugar, hence there is little or no gas formed in cases where an incision or a section will show abundant bacilli.

The explanation rests, I think, in the fact that the toxin of the bacillus will inhibit emigration and kill the leucocytes when present in large amount. This can be shown with the differential emigration chamber described above, using an old culture (48 hours), so as to get a powerful toxin; the addition of chalk is necessary, and even then not all cultures give a toxin powerful enough for the purpose. When the conditions are satisfactory very little emigration occurs in the specimen acted on by the toxin, in sharp contrast to that which is seen in the control specimen. (Fig. 3 A, Fig. 3 B.) And if we examine the material from the gangrenous region or from the wound which causes it and compare it with ordinary perfringens pus we are immediately struck with the difference. On the one hand, in the gangrene cases we find millions and millions of bacilli, but very few leucocytes, and those that are present showing evident signs of degeneration and solution (the bacillus is a proteolytic agent, though not a very powerful one). (Fig. 4.) In the pus, on the other hand, there are abundant healthy leucocytes, some with ingested bacilli,

FIG. 4.



Fluid from gangrenous limb. Notice the enormous number of bacilli and the scanty number of (degenerated) leucocytes.

and, compared with the gangrene fluid, very few bacilli. (Fig. 5.) Evidently, therefore, the toxin of B. perfringens, if sufficiently strong, no longer serves to attract leucocytes. I cannot say whether it repels them or no. I have seen nothing to suggest to me that any agent does so, although, of course, negative chemotaxis is well known amongst the lower animals and plants. But it kills them, as the opsonic experiment quoted above shows us, and this is sufficient for the purpose. If therefore toxin is formed in sufficient amount the defence of the body, as far as it is entrusted to the leucocytes, breaks down altogether; the leucocytes are not attracted to the infected region, and those that are there already, all too scanty as they are, are killed.

The question resolves itself into this: What are the conditions under which a great amount of toxin, an amount sufficient to paralyse the leucocytic defences of the body, can be formed in a short time? I have already mentioned the enormous rate of growth of the bacilli under favourable conditions, and this is nowhere better shown than in dead tissues. If a comparatively small dose (50 millions or less) of bacilli be injected into the ear vein of a rabbit, which is immediately killed and incubated, the number of bacilli in the internal organs, especially the liver, in three to five hours is extraordinary: a stained smear may look like a pure culture, thickly spread, and scarcely any cells may be visible. Dead blood (if I may use the expression) is an equally good culture-medium, and the heart-blood of the animal shows abundant growth. These are the two conditions we meet with in wounds: dead and lacerated

FIG. 5.

Pus containing B. perfringens. Notice the large number of healthy leucocytes and the small number of bacilli.

tissues, thoroughly inoculated with dirt, and a large blood-clot, very likely containing a piece of clothing with mud in its meshes. In either of these bacterial growth may take place unrestrained, and if there is no free escape for the toxin this may accumulate to such an extent that when it soaks through into the healthy tissues the leucocytes are killed on the spot, growth continues, and spreading gangrene is set up. This, of course, will be facilitated by any conditions interfering with the supply of blood; and in this connexion I must mention a fact first called to my attention by Captain Fitzmaurice Kelly, that gangrene frequently follows wounds of the forearm and leg, where the muscles are enclosed in fibrous aponeuroses, and are readily strangled if swelling takes place therein. A hæmorrhage into such a muscle, provided there were a heavy inoculation with perfringens, would be extremely likely to be followed by gangrene, since the pressure exerted by the hæmorrhage would render the muscle anæmic and so interfere with the leucocytic reinforcements on which the successful defence of the tissue depends. Hence, perhaps, the reason why gangrene usually begins in muscle, though it can subsequently spread anywhere.

Another point worthy of consideration is the fact that the toxin, when it reaches a vein, causes thrombosis, and thus the vascular supply is still further interfered with. The artery holds out much longer. And I am inclined to think that if there is any mechanical result from the gas, as Dr. Taylor suggests, it acts by occluding the veins. This might cause venous stasis above the region already infected.

While we differ on the pathology of the condition, Dr. Taylor and I agree (as, indeed, do all that have had experience on the matter) as to treatment. Early drainage, removal of clot and dead tissue, encouragement of the circulation—this is all that can be done, and is, I believe, sufficient.

A few more remarks on the general symptoms may be appended. There is a very marked leucocytosis (40,000 or more), as we should have expected; the toxin enters the blood stream, but is too dilute there to repel the leucocytes. There is very rapid blood destruction, so that a blood film presents an appearance suggestive of leucocythæmia, so abundant are the leucocytes in proportion to the red corpuscles. The polynuclears are mainly increased, and there is a very marked "shift to the left" in the Arneth count. The blood serum is tinged a bright yellow, and there is a very marked buffy coat.

Sir Almroth Wright has made some interesting observations, which he has kindly allowed me to quote, which show that there is a marked decrease in the alkalinity of the blood. There is a temptation to correlate this acidosis with the production of organic acids by the bacillus, and this is probably the correct explanation. Be this as it may, in two cases out of three in which the treatment was tried, he

obtained very definitely good results by the intravenous injection of 300 to 400 c.c. of 4 per cent. solution of sodium bicarbonate, this being followed by a rapid amelioration of the toxic symptoms. This is important, and well worth trying, as it rests on rational grounds and has been followed by very definitely good results.

I have to thank Colonel Sir Almroth Wright, A.M.S., in whose laboratories this work was done, for much helpful advice; Lieutenant H. H. Tanner, R.A.M.C.(T.C.), for his admirable drawings; and the Medical Research Committee, under whose auspices I had the opportunity of carrying out these investigations.

Harley-street, W.

THE VISUAL STANDARDS USED IN THE MEDICAL EXAMINATION OF RECRUITS IN THE BRITISH ARMY AND CONTINENTAL ARMIES.

BY J. V. PATERSON, F.R.C.S. EDIN.,
OPHTHALMIC SURGEON, ROYAL INFIRMARY, EDINBURGH;
AND
H. M. TRAQUAIR, F.R.C.S. EDIN.,
ASSISTANT OPHTHALMIC SURGEON, ROYAL INFIRMARY, EDINBURGH.

UP to the commencement of the present war the British army was organised largely with a view to its use in foreign countries at a great distance from its base. Under these circumstances the difficulties attendant on the provision of spectacles and their use by men on active service were overcome by the simple method of prohibiting glasses altogether, while by adopting a sight test conducted without glasses recruits with other than low errors of refraction were largely excluded. A recruit who failed to pass the test without glasses was finally rejected, no matter how good his corrected vision might be. At that time, and in the earlier stages of the present war, the standard was 6/24 with each eye, or 6/6 with one eye and 6/36 with the other.* With the increasing need for men, however, a modification was introduced, and in September of last year the standard was altered to 6/24 in each eye or 6/24 in the right eye with 6/60 in the left for general service, while 6/60 in the right with 6/24 in the left was accepted for the auxiliary services, the test being still conducted without glasses. The use of correcting glasses was, however, permitted in home service and garrison service at home and abroad, while steps were taken to supply correcting lenses to men who had joined the army and were subsequently found to be visually defective. While these modifications indicate a tendency on the part of the authorities to move in the right direction, an examination of the system adopted in the armies of the great continental powers, as given in the following table, will show how imperfect our system still remains.

A most striking and important feature in regard to these standards is the great similarity between them. France, Germany, and Austria have devoted the maximum of study and attention for half a century, if not longer, to their military organisation. Their collective experience must have made them thoroughly acquainted with the relationship of visual acuity to military efficiency, and we may be sure that they would not accept men for either combatant or auxiliary service who might be expected to prove useless or inefficient on account of defective eyesight.

In every case it is the vision with glasses or corrected vision which determines the acceptance or rejection of a recruit. In France, Germany, Austria, and Italy men with myopia as high as six or seven diopters (a recent letter from Valude, of Paris, gives the limit as seven to eight diopters) are accepted for combatant service provided that the vision with glasses reaches the required standard. It must be remembered that the uncorrected vision of a man with six or seven diopters of myopia will not be more than 3/60 without glasses. Contrast this vision with that required by the British regulation for general service—namely, 6/24 in each eye, or 6/24 in the right with 6/60 in the left *without glasses*, corresponding to 2·5 and 3·5 D. of myopia at most.

Although the British standard is that indicated above—and we are unaware of any new standard since September, 1915—a modification has been adopted within the last few months, as is evident from a statement recently made in the House of Commons by Mr. Tennant to the effect that "recruits for the British army whose standard of vision does not come up to that required for general service are not rejected, but are utilised where it is thought their services would be most valuable, provided that they can see with glasses to shoot." This statement leaves the standard for general service as it was, so that all myopes with as low a defect as 3·5 D. in the worse eye are excluded from combatant service in our army, though not in the armies of France, Italy, Germany, and Austria. In regard to hypermetropia and astigmatism the regulations of continental armies follow similar lines, while here again in our army men with such refractive errors are excluded from general service, unless they can pass the sight test without glasses.

The main defects of the British system in the order of their importance are the following: 1. The prohibition of the use of glasses during the test, thus making the uncorrected vision the standard of visual efficiency. 2. The insistence on an arbitrary and unnecessary standard of vision in the worse eye when the sight in the better eye is good. 3. The failure to ascertain by the test whether any visual defect present is caused merely by a refractive error corrigible by glasses or by organic disease of the eye.

* Swanzy: Diseases of the Eye, eleventh edition, p. 626.

Table showing the Visual Standards for Recruits in the Chief European Armies.

—	Amount of short sight (myopia) allowed.		Standard of corrected vision.		Remarks.
	Combatants.	Non-combatants.	Combatants.	Non-combatants.	
GERMANY	6·5 D. For Landsturm no limit if standard of corrected vision attained.	—	1/2 in better eye. Other eye may have minimal vision. For Landsturm vision = 1/4. If one eye has vision = 1/2 the other may be blind.	—	Vision with glasses (corrected vision) counts.
AUSTRIA...	6 D.	Above 6 D. no limit if standard of corrected vision is attained.	Group 1, 1/2 in each eye. Group 2, 1/2 in one; 1/4 in other.	1/4 in one; 1/10 in the other.	Vision with glasses counts.
FRANCE...	7 D.	Above 7 D. no limit if standard of corrected vision attained.	1/2 in one eye; 1/20 in the other.	1/4 in one eye; 1/20 in the other.	Vision with glasses counts.
ITALY ...	7 D.		1/3 in each eye, or 1/12 in one eye if the other has 1/1 (full vision).		Vision with glasses counts.
GREAT BRITAIN	No amount specified, but according to vision required highest amount possible is about 2·5 D.	No amount specified, but according to vision required highest amount possible is about 2·5 D. in better eye and 3·5 D. in worse eye.	No correction allowed for general service. Uncorrected vision must be 1/4 in each eye, or 1/4 in the right eye with 1/10 in the left.	Uncorrected vision must be 1/4 in better eye, 1/10 in worse eye. The better eye may be the left.	Vision without glasses counts. For home service, garrison service, and garrison service abroad glasses are allowed within unspecified limits.

Notes.—1. The standards in the table are peace standards, except that of Great Britain, which is a war standard and by far the highest. 2. Three diopters of myopia will reduce the vision to below the British army standard in practically every case. 3. The regulations in continental armies as to forms of refractive error other than myopia follow similar lines.

1. The continental powers take the view that it does not matter very much what a recruit's vision is without glasses, provided that he gets 6/12 vision in the better eye with spectacles. They simply neglect the uncorrected vision in cases in which it can be improved by glasses—in fact, they apply to their military service the practice which holds good in civil life where no one is considered to be disabled by his sight if his corrected vision is moderately good. As suggested in the beginning of this paper, it is easy to see why in previous times recruits for the British army were accepted on a test of uncorrected vision; it is not easy to understand why this principle should be adhered to at the present time when it has become necessary to utilise every available man and our main army is fighting in allied and adjacent countries.

2. In the British army the standard for general service requires vision of at least 6/60 in the worse eye, which must be the left. This means, first of all, that there may not be a refractive error of any kind which in its uncorrected condition reduces the vision in this eye to below this level no matter how good the corrected vision may be. Secondly, this regulation excludes from general service a considerable number of men who have very defective vision in one eye (e.g., certain cases of squint, corneal scarring, &c.), although the vision of the other eye may be excellent. These men are often unconscious of any visual defect, and in civil life their fitness for work is never questioned. In Germany combatants are required to have corrected vision of at least 6/12 in one eye; in the other the *corrected* vision may be minimal, and in the Landsturm the second eye may even be blind. It must be obvious in any case that a man with good vision in one eye and vision even much below 6/60 in the other is much more likely to prove efficient than a man whose vision in each eye is only 6/24. Yet under the present arbitrary regulations the former is excluded from general service even if his good eye is the right, while the latter is presumed to be visually the better of the two. In regard to such cases it cannot be too strongly emphasised that the continental powers are unanimous in the adoption of a practice essentially different from that of the British army.

3. A sight test based on uncorrected vision and with a standard of 6/24 and 6/60 also fails to differentiate between cases of defective vision due to refractive errors and those due to organic disease of the eye. While this question is of less importance, a considerable number of men visually unfit for soldiering do pass the test. We have ourselves seen cases of cataract, optic atrophy, and very bad corneal opacities which must have been present before enlistment and which were the cause of men being invalided home from the front. More numerous are the hypermetropes who pass the test while they are well and strong, but who, after some months of trench life and perhaps a wound, find that their visual acuity is seriously reduced owing to difficulty in maintaining accommodation.

It was stated in the House of Commons on March 16th last that the British visual standard was fixed by a mixed committee of military officers and ophthalmic experts. We are confident that British ophthalmic surgeons will be found practically unanimous in condemning the present system and we are informed by the Ophthalmological Society of the United Kingdom that they have not been consulted since 1906.

In collecting information as to the sight tests in other countries we were strongly impressed by the fact that for scientific studies of the vision required for shooting and for general military service it is necessary to go to foreign literature, as nothing of this kind appears to have been undertaken in Great Britain. We have been unable to find any reference to the subject in English medical literature, whereas it is fully discussed in continental journals by numerous writers, amongst whom Scherer, Steiger, Coullaud and Ginestous, Lagrange and Cuny may be mentioned. In some of their papers extensive bibliographies are given without mention of a single English work. This absence of military ophthalmology in Great Britain is as regrettable as it is important, and may undoubtedly be attributed in great measure to the operation of a sight test for recruits conducted without glasses, and which excludes without question cases of bad sight in one eye only.

As far as shooting is concerned, it is generally agreed that vision of 6/12 at least is necessary, and on the continent it is believed that a soldier with 6/12 vision wearing glasses is more efficient as a combatant than another with 6/24 vision without glasses. Continental authorities have found that on the average soldiers who see best shoot best, and that those who wear correcting spectacles shoot better than those who do not.

Summary.

1. The present sight test for general service for recruits for the British is by far the highest in Europe, and excludes from the fighting line large numbers of men who are freely used as combatants in the armies of the chief continental powers.

2. This is due to the fact that in the British sight test the vision without glasses (uncorrected vision) is what counts, whereas in the chief continental armies it is the vision with glasses (corrected vision) which counts.

3. In view of the present want of men there is urgent need for the immediate adoption of a remodelled sight test based on corrected vision, on the lines of the military visual standards in use on the continent of Europe.

SPINAL ANÆSTHESIA, WITH SPECIAL REFERENCE TO THE USE OF NOVOCAINE.

BY C. COLGATE HOLMAN, M.B., B.C. CAMB., F.R.C.S. ENG.

THE employment of novocaine as an agent for inducing spinal anæsthesia has been advocated by Canny Ryall.[1] More recently two series of prostatectomies in which this drug was employed have been published by Page[2] and Mortimer[3] respectively. These two articles are of special interest, as the writer in each case is an anæsthetist and not a surgeon.

Prior to using novocaine I had used Barker's stovaine-glucose solution in some 30 cases. Experiments carried out by Le Brocq[4] led me to expect that in novocaine I should find a drug almost equal to stovaine in anæsthetic action and considerably less deleterious to the patient. Le Brocq, working with rabbits, found that if the toxicity of cocaine was taken as the standard unit then the toxicity of stovaine was 0 625, of novocaine 0·490. Injection of a 10 per cent. solution of stovaine caused intense hyperæmia of the tissues followed by sloughing. After injection of a 10 per cent. solution of novocaine there was no swelling and no hyperæmia; the part appeared normal and remained so. The preparation used in this series of over 300 cases was a 5 per cent. solution of novocaine and mannitol. The dose employed for an adult varied from 6 cg. to 8 cg. of novocaine.

Technique.—The injection was in every case made with the patient lying on his side with knees drawn up and back rounded. Barker's syringe was used. Puncture was usually made in the second or third lumbar interspace in the mid-line. In the earlier cases 3 or 4 drachms of cerebro-spinal fluid were allowed to escape before the injection was made, in the later cases a few drops only. If anæsthesia did not reach a sufficiently high level in five minutes the table was tilted. Failure to withdraw cerebro-spinal fluid occurred twice in the last 200 cases; in one case the needle was too short. In some cases several attempts had to be made before success was obtained, and occasionally lateral puncture succeeded after median puncture had failed. It is useless to make an injection unless a flow of cerebro-spinal fluid is obtained. Tingeing of the first drops by blood is of no importance, but if pure blood flows from the needle a fresh puncture should be made. A flow of pure blood occurred on a few occasions only, and in no case was it followed by any untoward symptoms. In nearly 4 per cent. of cases

anæsthesia after a successful puncture was absent or insufficient. This was generally remedied by giving a second injection, and in no case did any ill-result follow. Probably by some error in technique the first dose had failed to reach the proper spot. The average duration of anæsthesia was about one hour. On 4 occasions a second injection was given at the end of periods varying from one to one and a half hours after the first. The second dose was half the amount of the first. Results were satisfactory. In most cases anæsthesia reached to about the level of the umbilicus; in a few cases as high as the second rib. On 4 occasions, after an operation had been started successfully under spinal anæsthesia, a general anæsthetic had to be given for a varying length of time.

Operations for which spinal anæsthesia was used.—In the majority of cases the site of the operation was below the level of the umbilicus—e.g., for hernia, hæmorrhoids, and varicose veins. Anæsthesia in the case of the two latter was always perfect. In operating on varicose veins spinal anæsthesia is specially useful, as the patient can lie in any position convenient to the surgeon. Some of the hernias were very large, and silver filigrees were used. Patients frequently complain of a dragging sensation in the chest when the neck of the sac is being pulled upon, but this seldom amounts to more than a passing discomfort. There was one case of suprapubic prostatectomy, an old man, aged 77, who distinguished himself by walking to the lavatory two hours after the operation. He was none the worse for the venture. This patient received a dose of 7·5 cg. of novocaine, so that it seems somewhat unjust for a surgeon to blame the method because a man aged 68 dies a few hours after receiving a dose of 15 cg. for a similar operation.[5] As regards abdominal operations proper, there were 8 cases of appendicectomy, in one of which chloroform had to be given for ten minutes, 4 cases of umbilical and 1 of ventral hernia, and 1 case of intestinal obstruction.

Type of patient.—The majority of patients were males, and their ages varied between 14 and 77. One patient was a medical man who had a dread of general anæsthesia. He underwent an operation for piles under spinal anæsthesia and was pleased with the procedure. My impression is that the best type for spinal anæsthesia is the stout alcoholic patient who often takes general anæsthetics badly. The thin nervous subject frequently complains of feeling faint at the beginning of the operation and is more liable to complain of unpleasant sensations if the peritoneum be pulled upon.

Symptoms occurring during the operation.—Faintness, often accompanied by nausea or vomiting, is common during the first ten minutes. It is usually relieved by half an ounce of brandy or a hypodermic injection of strychnine. Vomiting while on the table was noted in 4 per cent. of cases. The series includes several cases of strangulated hernia, and on nearly every occasion the bowels acted on the table after the constriction had been relieved. Serious symptoms never occurred in patients under 50 years of age, but there was more than one case of alarming syncope in older subjects. The weak point of spinal anæsthesia is that one has to give a more or less fixed dose of a potent drug, and no allowance can be made beforehand for the idiosyncrasy of the patient. I agree with Canny Ryall[1] in thinking that serious symptoms are directly due to the poisonous action of the drug on the nervous centres. This action is best combated by hypodermic injection of strychnine or, if this fails, by intravenous infusion of saline. I have not tried injecting strychnine into the spinal canal according to the method of Jonnesco, but the uniformly safe results claimed by this surgeon have not been obtained in this country. The matter under discussion is of so much importance that I will give notes of the more severe cases. No death occurred which could be directly attributed to the anæsthetic in the case of novocaine, but I am of the opinion that this drug is no safer than stovaine because its lower degree of toxicity is neutralised by the fact that a larger dose is required.

CASE 1.—A man aged 70, who had recently had half his tongue removed for cancer, was admitted suffering from a strangulated inguinal hernia. An injection of 6 cg. stovaine was given in the lumbar region. During the operation he lost consciousness and his pulse could not be felt. An intravenous infusion of saline was given and he rallied temporarily, but died 12 hours later. It is generally agreed at the present day that this type of case should be operated on under local anæsthesia.

CASE 2.—A female, aged 55, was admitted suffering from a strangulated hernia. A hypodermic injection of morphine gr. 1/6 with hyoscine gr. 1/150 was administered and followed by a spinal injection of 5 cg. stovaine-glucose. Three minutes afterwards she became unconscious, with shallow respirations and feeble pulse. She improved after injectio strychninæ hypodermica ♏x, but did not recover consciousness until the operation was finished. There were no subsequent ill-effects.

CASE 3.—Male, aged 53. A thin, unhealthy-looking man who had suffered from a tape-worm for about a year. He was admitted on account of a small hernia of the linea alba situated above the umbilicus. He said this caused him much pain and that he suffered from vomiting and constipation, but it is questionable whether these symptoms had any connexion with the hernia. A dose of 8 cg. novocaine was injected, and anæsthesia rose to about the level of the hernia. Five minutes after the injection he became faint and vomited foul-smelling material. He became rapidly worse and lost consciousness. The pulse could not be felt. Injectio strychninæ hypodermica ♏vij was given, followed by oxygen inhalations and a pint of saline intravenously. He rallied after the infusion and recovered consciousness in about ten minutes. An action of the bowels took place on the table. The operation was concluded without further trouble, and there were no after-effects.

CASE 4.—Male, aged 53. Operation for radical cure of inguinal hernia. Dose of novocaine 8 cg. Fifteen minutes from the start patient became faint and said he could not see. Pulse and respirations were very feeble. He improved after injectio strychninæ hypodermica ♏x. There was no further trouble.

Similar cases occurring after stovaine are recorded by Barker,[6] Milward,[7] Owen Richards,[8] and Madden[9]; after tropacocaine by Morrison[10]; and after novocaine by Mortimer.[3] The occurrence of such cases is disappointing, because many patients who appear to be equally bad subjects take spinal anæsthesia without a bad symptom. One case in particular impressed me. The patient was a man aged 66 suffering from diabetic gangrene. He was stout, cyanosed, and dyspnœic. After being placed on the table he was scarcely able to move without help. An injection of 7·5 cg. of novocaine was given and amputation through the thigh performed without a single bad symptom. He died 36 hours later, but death did not appear to be in any way connected with the anæsthesia.

Serious symptoms seem to occur most often in old and enfeebled patients, especially in those suffering from intestinal obstruction of long standing. I should hesitate to use spinal anæsthesia in the case of patients suffering from shock following severe injuries, although some authorities recommend it. The best treatment seems to be immediate intravenous infusion of saline. My impression is that in the case of old or debilitated patients an injection of strychnine before going to the operating theatre is useful as a prophylactic. One elderly patient underwent two operations for large herniæ. On the first occasion operation took place on the day after admission and he became markedly faint. The second operation was done after he had had three weeks complete rest in bed and he showed no trace of faintness.

After effects.—Backache and retention of urine appear to be less common than after a general anæsthetic. Some authorities express a contrary opinion. Headache is often troublesome during the first 48 hours. In my first 98 cases, thinking that headache might be caused by increased tension of the cerebro-spinal fluid, I allowed 3 or 4 drachms of fluid to escape before making the injection. Headache occurred in varying degree in 42 per cent. of these cases. In the later cases I allowed only a few drops of fluid to escape. Headache followed in 21 per cent. It was usually slight and relieved by aspirin. The figures are not large enough to be of much value, but it is reasonable to suppose that if one is injecting about 1 c.c. of solution it is best not to allow more than that amount of fluid to escape. My attention was first directed to this point by several cases, occurring among the early ones, in which the patient was comfortable while in bed, but complained of headache, faintness, and giddiness for several days after getting up. I attribute these symptoms to disturbance in the tension of the cerebro-spinal fluid. An instructive case occurred amongst the earliest ones, in which I employed stovaine. A man aged 44 was given 4 cg. of stovaine-glucose in order that some adhesions in his knee-joint might be broken down. He was kept in bed for 48 hours, and as he had no bad symptoms he was allowed to return home.

He was readmitted in a few days suffering from very severe headache and pain in the back of the neck. All symptoms cleared up completely after further rest in bed. A rise of temperature to over 100° F. occurred in a few cases, but this is not uncommon after general anæsthesia.

Permanent after-effects are very rare. I wrote to a large number of patients nine months after operation and only two made any complaint. One man who had undergone an operation for piles wrote that the operation was quite satisfactory, but that he had suffered terribly with his nerves since. The other said he suffered from aching pain in the back. None of the terrible sequelæ recorded by continental surgeons was observed.

In conclusion, I would emphasise the fact that spinal anæsthesia is a method which must be employed with scrupulous care and attention to detail. It is more suitable for use in hospitals where the nursing staff is familiar with the technique and after-treatment, than it is for casual operations in private practice. Like many valuable operations it has sometimes obtained a bad reputation through improper performance. Whether novocaine has any special advantage over stovaine I am not prepared to say. Its lower toxicity is neutralised by the fact that a somewhat larger dose is required. That it is less irritant to the tissues is, I believe, generally admitted.

THE CLINICAL MANIFESTATIONS OF GAS IN MILITARY MINES.

BY C. E. SUNDELL, M.R.C.S. ENG., L.R.C.P. LOND.,
TEMPORARY CAPTAIN, R.A.M.C.

THE following notes are mainly based upon a series of over 100 cases which have passed through my hands during the last few months. I have to acknowledge much valuable help in the study of this subject from Captain Logan, R.A.M.C., who has generously placed the results of his extensive experience at my disposal.

"Gassing" is responsible for the great bulk of casualties among miners following the explosion of a charge. Military mining differs from industrial mining in three particulars which are of importance in the present connexion. The charges used are very much larger, the air space of the mine is very much smaller, and adequate ventilation of the shafts and galleries is much more difficult to maintain. The harmful gas produced by an explosion may for practical purposes be regarded as consisting only of carbon monoxide; nitrous fumes are also present and may cause irritant effects in some cases, but these are relatively unimportant. The quantity of carbon monoxide produced by the explosion of a mine charge is considerable; if, as sometimes happens, the explosion is incomplete and part of the charge burns instead of detonating, the carbon-monoxide production is much increased. It is remarkable that in the area with which I am familiar more casualties occur during the few days subsequent to the explosion of a hostile mine than at the time of the explosion itself. This is to be explained by the friable nature of the chalky soil in which the mine is sunk; the force of the explosion fissures and shatters the soil throughout a wide zone, and in the crevices thus formed the gas collects till it is freed by fresh working or puffed out into the galleries by gradual settling of the soil.

The following characters of carbon monoxide should be borne in mind: the gas is odourless, it does not affect a candle flame, its presence in the atmosphere at a strength of 0·1 per cent. may be fatal, and its action is cumulative. Men may thus gradually come under its influence without any warning of its presence.

Premonitory symptoms.—These may be absent; in many cases, however, warning is given by a feeling of heaviness and loss of power in the limbs, especially in the hands and arms; sometimes the first complaint is of giddiness or light-headedness. The loss of limb-power is important, as it may prevent escape or lead to falls from the ladder while the man is attempting to climb out of the mine. All degrees of severity are met with, from transient disability to complete collapse and death; fortunately the cases of moderate severity are the most common.

Appearance of the men.—Other observers lay stress upon the pink colour of the cheeks and lips, and the appearance of cherry-red patches upon the skin of the chest and back have been described; in my own cases, all of which have been seen without delay, pallor has been constant; a recent writer had called attention to the occasional late appearance of the classical pink tint in fatal cases of carbon-monoxide poisoning.

The *attitude* in the cases able to walk to the aid-post is very striking: it is that of extreme physical and mental fatigue. The men crouch on a bench with elbows on knees and supporting their heads in their hands; they show a great disinclination to speak or move. The mental state varies, however; sometimes considerable mental excitement is present, suggesting a thoroughly happy "drunk."

Pulse-rate.—In mild cases this is unaltered or slightly raised. In severe cases it may rise to 140 or more, while Captain Logan has told me of one case in which the patient was found unconscious and convulsed, with a pulse-rate of 38–42 beats per minute.

Temperature.—The patients, even when only slightly affected, are cold. This is partly due to the fact that they are brought thinly clad from the close atmosphere of a mine into the open air; but it is an established fact that carbon-monoxide poisoning is always associated with lowering of the body temperature. In bad cases severe rigors may occur.

Respiration.—In mild cases this is slightly increased in rate; in severe cases it is slowed or abolished.

Vomiting is an almost constant symptom; it occurs usually when the man is brought out into the fresh air, and it frequently affords relief to his feeling of weakness or giddiness.

Headache comes on usually on exposure to fresh air; it is often very severe and is usually frontal in position. It is one of the most lasting of the symptoms, and may persist, even in a mild case of poisoning, for over seven days.

Præcordial pain is not a very common symptom, it may occur with palpitation and a throbbing headache. It has been found, however, in a good many cases, especially in men who have repeatedly been exposed to gas; in these men other phenomena of heart fatigue may be present, such as superficial præcordial tenderness and undue breathlessness on exertion.

Nervous phenomena.—Psychical or physical changes may ensue upon repeated exposure to gas. Several men who originally possessed more than the average of pluck and determination have "lost their nerve" and developed insomnia, tremor of hands, and weakness of will power.

Treatment.—This may be summed up in warmth, oxygen, artificial respiration, rest. The lowering effect of CO upon the body temperature has been referred to; every effort should be made to provide warmth for these men with the least possible delay. Circulatory stimulants, such as hot strong coffee, are of great value.

Oxygen administration properly carried out is most beneficial; a well-fitting mask and a liberal amount of gas are necessary. It is possible that oxygen tends to wash out CO from the blood; whether this be so or not, it is a most valuable help towards recovery.

Artificial respiration should be carried out, if circumstances allow, by Schäfer's method; this allows of continuous oxygen administration, and can be employed with the minimum of fatigue to the attendant. Prolonged and unremitting efforts may be necessary; I have seen recovery take place after two and three-quarter hours' apparently fruitless work. Some cases begin to breathe spontaneously after a time, and then suddenly slip back and fail to respond to further efforts. Hypodermic injections of strychnine are of value in stimulating the respiratory centre.

Rest is essential; it should be absolute for at least 24 hours, even in mild cases, and proportionately longer in the more severe.

Practical experience affords two warnings. Severe cardiac embarrassment has followed the taking of phenacetin and aspirin for the severe headache. The use of these drugs in these cases is now forbidden.

Men who have been slightly gassed should not be allowed to descend the shaft again till recovery is complete; the cumulative action of carbon monoxide must never be forgotten.

ON FOREIGN BODIES IN THE BLADDER RESULTING FROM GUNSHOT WOUNDS.

BY G. GREY TURNER, M.S. DURH., F.R.C.S. ENG., &C.,
MAJOR, ROYAL ARMY MEDICAL CORPS (T.F.).

THE annotation on the above subject in THE LANCET of Dec. 18th, 1915 (p. 1361), suggests the publication of the following cases:—
